Pseudocowpox is a common parapoxvirus of cattle related to the viruses of contagious ecthyma (soremouth) of sheep and goats and bovine papular stomatitis (see Chapter 32 for these diseases). All three parapoxviruses may cause nodular lesions on humans. The lesions of pseudocowpox are usually confined to the teats of cattle, and the disease is common worldwide. Cyclic waves of reinfection occur in a herd, where it causes minor teat lesions characterized initially by a small papule 2 to 3 mm in diameter, followed by crusting and circular spread of the lesion. Approximately 10 days later, the 15- to 20-mm lesion appears as a ring or horseshoe-shaped scab.[99] Lesions occasionally involve the udder, medial thighs, or scrotum. Deep ulceration is rare. There are no systemic signs of illness.[29] The major problem associated with the teat lesions is an increased incidence of mastitis. The most important and common differential diagnoses are bovine herpes mammillitis and viral papillomas. Rare viruses involving the teat include vaccinia and cowpox.[99] Cowpox is a rare disease of cattle in Europe that causes ulcers and may also produce lesions in humans. Vesiculation is rare in pseudocowpox, in contrast to bovine herpes mammillitis, vaccinia, and cowpox.[29]

40.23 BOVINE HERPES MAMMILLITIS (BOVINE HERPESVIRUS, BOVINE ULCERATIVE MAMMILLITIS)

Bovine mammillitis teat lesions are caused by bovine herpesvirus type 2 (BHV-2), which is widely disseminated in most cattle populations.[100,101] The disease may be epidemic or endemic. The virus may also cause oral lesions, udder lesions, or generalized skin disease in cattle. The teat lesions start as swollen, tender, edematous teats. Vesicles may appear in some lesions, whereas others ulcerate almost immediately. The teats become painful, and ulcers require 3 to 10 weeks to heal.[100,101] Mastitis is increased because the scabs on the teats are laden with bacteria. Diagnosis may be confirmed by isolation of the virus, the BHV-2 serum neutralization tester, or histologic demonstration of herpesvirus particles.[100,101] Therapy consists of segregation of affected animals from the rest of the herd, and affected cows should be milked last. Milkers should wash hands between cows. In severe cases, secondary infection may be controlled by topical antibiotic creams or parenteral antibiotics, with proper residue avoidance precautions in place.

40.24 SHEEPPOX AND GOATPOX

Sheeppox and goatpox are caused by capripoxviruses.[102] Both occur in Africa, Asia, and the Middle East; goatpox also occurs in parts of Europe and the United States. The two diseases are clinically similar, although sheeppox has the most severe systemic signs of the animal pox diseases. However, recent studies have showed that the viruses are phylogenetically distinct and can be differentiated by molecular tools.[103] The diseases affect all ages, causing pyrexia, anorexia, conjunctivitis, rhinitis, and skin lesions. Prophylaxis using attenuated vaccines is the preferred control measure because the immunity is long-lasting.[102,103] Morbidity is high. Mortality may reach 80% with sheeppox but usually is low with goatpox. Humans may develop skin lesions from goatpox.

40.25 FUNGAL DISEASES

STEPHEN D. WHITE

40.26 DERMATOPHYTOSIS (RINGWORM)

Dermatophytosis refers to infections of the keratinized tissues of the skin (stratum corneum layer of epidermis, hair, claws, hoof, and horns) by *Microsporum* and *Trichophyton* species. Dermatophytosis is relatively common in the horse and in cattle, less so in goats, and rare in sheep.

40.26.1 Etiology and Pathogenesis

The most common equine dermatophyte species isolated from horses are *Trichophyton equinum, Microsporum equinum, Trichophyton mentagrophytes,* and *Trichophyton verrucosum*.[7,28,104] *T. verrucosum* infections in humans caused by transmission from horses have been reported.[105] In ruminants the majority of dermatophytosis lesions are caused by *T. verrucosum* and to a lesser extent by *T. mentagrophytes*. The transmission of the disease is usually from animal by direct contact or indirectly through fomites such as grooming instruments, tack, housing, fencing, or feed bunks. The incubation period may range from 1 to 6 weeks.

Several factors may influence the susceptibility of an animal to dermatophyte infection. Age is probably most important, with younger animals more susceptible to infection. The susceptibility of young animals is most likely related to lack of prior exposure/infection and thus no immunity, as well as crowding of young animals and conditions that decrease resistance to infection (e.g., poor nutrition). Environmental factors such as warmth and humidity also may play a role. Calves kept indoors or exposed to foggy weather with little or no sunlight have an increased incidence.

1318

1319

Under normal circumstances, dermatophytes only invade fully keratinized, nonliving tissues.[7] This results in weakened hair shafts, leading to alopecia.

In many cases, dermatophytosis is theorized to be a self-limiting disease, with the duration of infection ranging from 1 to 4 months. The spontaneous regression is at least partly related to the development of immunity, of which cell-mediated immunity is the more important. The immunity that develops is probably not complete, and its duration is unknown.

40.26.2 Clinical Signs

The lesions are often circular and usually appear first on the face or in the axillary/girth area and may spread over the trunk, rump, neck, head, and limbs (Fig. 40-10). Occasionally in the horse, dermatophytoses may be limited to the pastern region. Rarely, dermatophytes may be a cause of coronary band disease in horses. The mane and tail are rarely involved. Cattle and goats are frequently affected around the eyes and face (Fig. 40-11).

Lesions may be superficial or deep. Superficial infections are much more common and manifest with the development of thick crusts or more generally a diffuse moth-eaten appearance with desquamation and alopecia, sometimes in a ring pattern. A small crust may form over the follicle, and the hair is lost. Occasionally the initial lesions may be urticarial, progressing to multifocal, sharply demarcated areas of alopecia and scaling.

The degree of pruritus varies but is usually mild or absent. Erythema is usually absent or obscured by pigmented skin. The lesions in cattle are usually characterized by excessive crusting, taking on an almost wartlike appearance.

Fig. 40-10 Ringworm lesion in flank area of a horse (*Trichophyton* species).

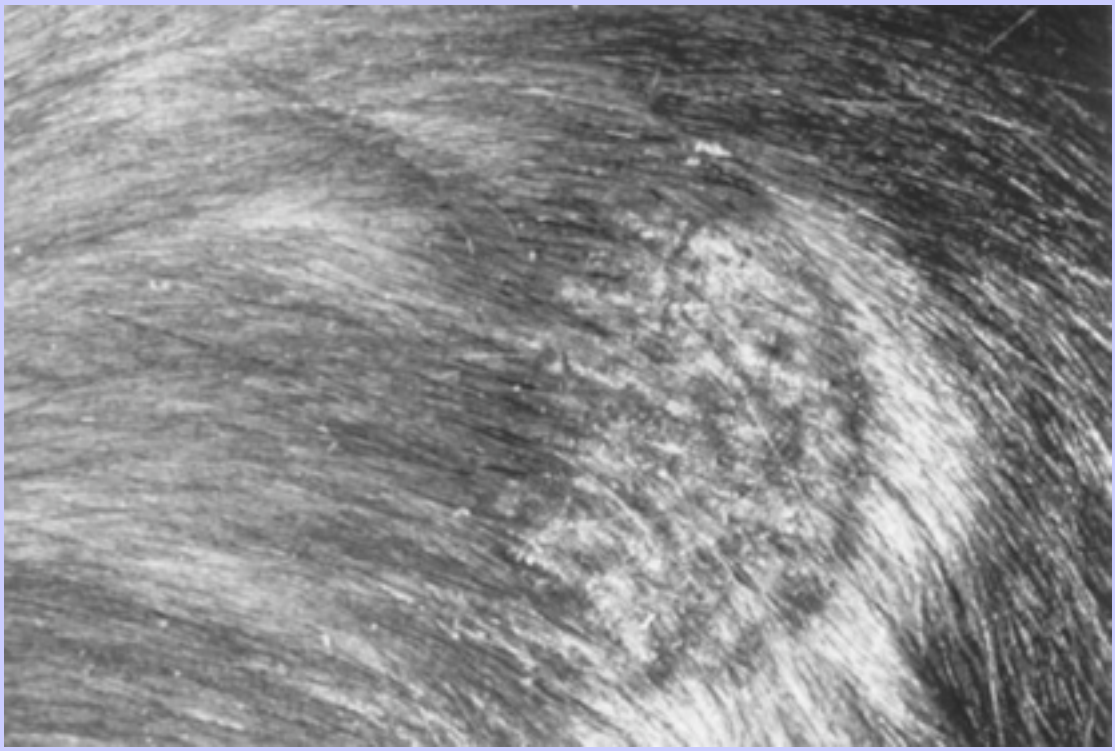

Fig. 40-11 Ringworm lesions around the eye of a calf, caused by *Trichophyton verrucosum*.

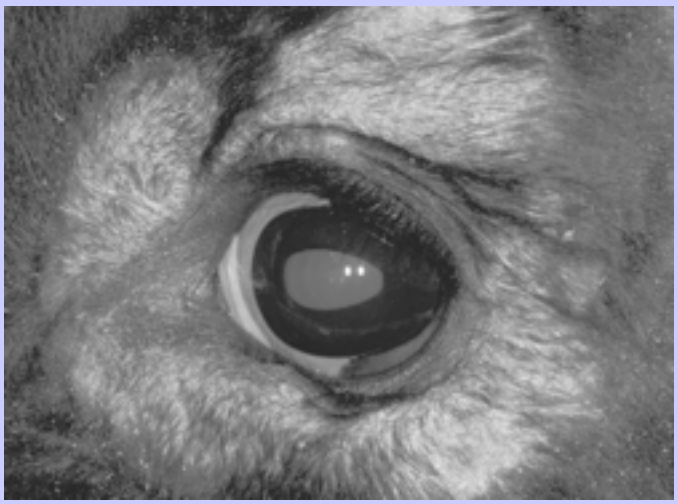


Dermatophytosis must be considered in the differential diagnosis of any dermatoses characterized by multifocal alopecia or scaling and crusting. For a solitary lesion in horses, the occult sarcoid is the primary differential diagnosis. The two most important differential diagnoses of more extensive lesions are dermatophilosis and pemphigus foliaceus.

40.26.3 Diagnosis

Direct microscopic examination of infected hairs is of value, but in general the most common and reliable method of diagnosing dermatophytosis is fungal culture (see Chapter 11). Broken hairs at the periphery of lesions are most satisfactory for this purpose. Large crusts and areas of separation should be avoided. The use of specialized indicator media is preferred. On occasion, dermatophytosis is diagnosed histopathologically. Interestingly, *Trichophyton* species occasionally may cause acantholysis, mimicking pemphigus foliaceus on histopathology.[106]

40.26.4 Therapy

Although 50% captan (2 tablespoons powder in 1 gallon water) has been recommended in the past and is certainly safe for tack, its effectiveness has been questioned. Lime Sulfur (LymDyp, IVX Animal Health, St. Joseph, MO), 1 cup to 1 gallon of water, and bleach 1:10 with water are both effective, but messy, odiferous, and staining. Miconazole shampoos are becoming more widely used and may be as effective. In Europe and Canada an enilconazole rinse (Imaveral, Jaansen), approved for horses and cattle, is highly effective.

Systemic treatment is occasionally needed. The efficacy and proper dose of griseofulvin in horses has not been thoroughly researched. However, a dosage of 100 mg/kg daily for 7 to 10 days has been advocated and has been used with good success on a small number of horses by the author. Griseofulvin is a teratogen and should not be used in pregnant mares. Alternatively, 20% sodium iodine (NaI) may be given IV (250 mL/500-kg horse once or twice every 7 days) but also is contraindicated in pregnant mares because it may cause abortion.[28]

Vaccinating cattle against *T. verrucosum* has long been successful in Eastern Europe and Scandinavia. Effective control of ringworm in cattle has been achieved in regions implementing systematic vaccination.[107] Vaccination against *T. equinum* in horses may reduce the incidence of new infections and protect a high percentage (>80%) of vaccinates from infection. These data are based on results with an inactivated vaccine containing both conidia and mycelial elements.[108] In cattle, newer vaccines consisting of recombinant protein and deoxyribonucleic acid (DNA) derived from heat-shock protein 60 of *T. mentagrophytes* have shown success experimentally.[109] Such vaccines are not yet available in the United States.

40.27 SPOROTRICHOSIS

Sporotrichosis is caused by the yeast *Sporothrix schenckii*, which is most common in vegetation. The yeast becomes pathogenic in animals as a result of its dimorphic ability to convert from a yeastlike form at (tissue) temperatures between 35° C and 37° C (95° F and 98.6° F) to a mycelial phase (with branching, septate hyphae) at environmental or laboratory temperatures of 25° to 30° C (77° to 86° F).[110] The disease has been reported in many species of domestic animals.

The initial lesions are nodules, which frequently ulcerate, and the disease may progress to a lymphatic-cording disease. Rarely, the fungus will eventually spread to the lungs. Diagnosis is made by demonstrating the organism on histopathology, immunofluorescent antibody testing on affected tissues, impression smears, and culture.[111] This is a zoonosis, so care should be taken in handling suspected samples.

Successful therapy with a number of different systemic iodine preparations (NaI, KI) has been reported. The organic iodides have proved to be superior in efficacy to the inorganic iodides in the treatment of equine sporotrichosis, with ethylenediaminedihydroiodide* being the drug of choice. This product is in the form of a feed additive and can be mixed with a small amount of grain and administered at 1 to 2 mg/kg of the active ingredient once to twice daily for the first week, then 0.5 to 1.0 mg/kg once daily for the remainder of the treatment. In general, lesions will begin to regress during the first month of treatment, and therapy should be continued for *at least 1 month* beyond the complete resolution of all cutaneous nodules and the healing of any ulcerated lesions. Discontinuing therapy prematurely will invariably result in an unnecessary relapse of the disease. During treatment the horse should be closely observed for any evidence of iodide toxicity (iodism), which includes excess scaling and alopecia, a serous ocular or nasal discharge, excess salivation, anorexia, depression, coughing, nervousness, or cardiovascular abnormalities. Should any of these signs develop, the treatment should be discontinued for 1 week, then resumed at three-quarters the dosage at which the iodism was noted. In most cases the treatment is subsequently well tolerated.[112] Although both itraconazole and terbinafine have been shown to be effective in vitro against the organism isolated from a horse, I am unaware of any clinical reports in this species.[113]

* Organic iodide powder, Neogen Corp, Lexington, KY, or EDDI 20 Gr. Dextrose base, Vedco, 5503 Corporate Dr, St. Joseph, MO.

40.28 PHAEOHYPHOMYCOSIS

Phaeohyphomycosis is actually caused by a number of ubiquitous fungi that are either saprophytes or plant pathogens. These include *Alternaria, Dreschlera, Cladophialophora, Cladosporium, Phialophora,* and *Stemphylium* species. The correct terminology currently depends on the histologic appearance of the organism, as follows[114]:

- *Chromomycosis:* Any pigmented fungi.
- *Chromoblastomycosis:* Pigmented fungi, primarily yeast.
- *Phaeohyphomycosis:* Pigmented fungi, both hyphal elements and yeast.
- *Hyalohyphomycosis:* Nonpigmented fungi, mainly hyphal elements.

Cutaneous lesions arise from either trauma to the skin or disseminated disease. Animals with disseminated disease probably have a deficient immune system. Similar to the other deep mycoses, these lesions present as expanding nodules and draining tracts. Diagnosis is by biopsy or occasionally cytology. Histopathology shows foamy or epithelioid macrophages, and special stains will show the organisms. Veterinarians and their staff should be careful in handling material from infected animals, because the inadvertent inoculation of these organisms can cause human infections.

Treatment has generally included surgical excision or amputation if practical. Potassium iodide (PI), as for sporotrichosis, and (if the owners can afford it) fluconazole at 5 mg/kg may be effective.

40.29 ZYGOMYCOSIS

Similar to phaeohyphomycosis, zygomycosis is caused by a number of related fungal species that are ubiquitous saprophytes. Gastrointestinal and respiratory tract involvement is possible. Cutaneous lesions are thought to be caused by wound penetration. The disease typically occurs in tropical and subtropical areas. The two orders of Zygomycetes that cause disease are Mucorales, including the genera *Rhizopus* and *Mucor,* and Entomophthorales, including the genera *Conidiobolus* and *Basidiobolus*. Most cutaneous reports are in horses, although ruminants may have other organ systems affected.

The skin disease is ulcerative, nodular, and generally found on the trunk and neck. Generally, only one large nodule is present. Diagnosis is by histopathology and culture; a serum agar immunoprecipitation test has been useful in diagnosing conidiobolomycosis. Surgical removal, if possible, is preferred for treatment. Medical options include the iodides (not effective against the order Mucorales) and possibly the azoles or amphotericin B.[7]

40.30 PYTHIOSIS

Not a true yeast, but rather a protista, *Pythium insidiosum* is considered to be the causative agent of "swamp cancer," also known as "Florida horse leech," bursattee, and kunker. This organism is found in tropical and subtropical areas worldwide. The pythiosis lesion occurs most often on the limbs, abdomen, neck, and lips and consists of dense granulation tissue containing masses of yellow-gray necrotic tissue, which sometimes are calcified and often are present as cores in fistulae and are removable intact. Such masses are known as "leeches" or "kunkers." The granuloma ulcerates and extends peripherally and may reach a very large size in a short time; the overlying and adjacent skin is destroyed by both the inflammatory reaction and the self-mutilation by the horse. Important differential diagnoses are systemic fungal infections, habronemiasis ("summer sore"), and neoplasia. Although most reports in large animals are in horses, cattle and sheep may also be affected.[115,116]

Histopathologic examination of affected tissue reveals pyogranulomatous inflammation directly surrounding the organism. Isolation of organisms from the lesions is necessary for further identification and study, but histologic demonstration of the protozoa within tissues that are reacting to its presence is critical in establishing the causal relationship in an individual lesion. In obtaining culture, the kunkers are preferred to the actual tissue. For samples that cannot be processed immediately, acceptable handling techniques include storage at room temperature for up to 3 days, refrigeration for up to 5 days, shipping on cold packs, and storage in antibiotic solution, each combined with subsequent inoculation on selective media.[117] Recent advances in ELISA or molecular techniques offer better potential for organism detection and identification.[118] Wide surgical excision combined with immunotherapy has the best chance of success.[118,119]

40.31 PARASITIC SKIN DISEASES

STEPHEN D. WHITE

40.32 PEDICULOSIS

Lice are obligatory ectoparasites that are generally host specific. Adults and nymphs are seldom able to live more than a few days away from their host. Large domestic animals suffer from infestation with several species of lice that belong to the orders Mallophaga, the biting lice, and Anoplura, the sucking lice (Table 40-2).[120]

Table 40-2 Lice Associated with Large Domestic Animals

Host	Mallophaga (Biting)	Anoplura (Sucking)
Horse	*Bovicola (Damalinia) equiWerneckiella equi equi*	*Haematopinus asini*
Cattle	*Bovicola (Damalinia) bovis*	*Haematopinus eurysternus*
		Haematopinus quadripertusus
		Haematopinus tuberculatus
		Linognathus vituli
		Solenopotes capillatus
Goats	*Bovicola (Damalinia) caprae*	*Linognathus stenopsis*
	Bovicola (Damalinia) limbatus	*Linognathus africanus*
	Bovicola (Damalinia) crassipes	*Linognathus vituli*
Sheep	*Bovicola (Damalinia) ovis*	*Linognathus pedalis*
	Bovicola (Damalinia) capre	*Linognathus ovillusLinognathus africanus*

Clinical infestations are most apparent during the winter months and reflect efficient louse reproduction during the late fall and that summertime temperatures on body areas exposed to sunlight are too high for lice. Apparent "carrier" animals within a herd maintain populations during the "off" season and serve as a source for reinfestation of the herd during the fall.[120] The hallmark of infestation is pruritus, and many clinical changes result from self-trauma. The neck and tail are typically affected first,[121] but infestation and clinical signs may become generalized. The coat becomes dry and scaly. Patchy alopecia and crusted ulcerations result from excoriation. A heavily infested animal may become anemic. Significant hide damage occurs as a result of excoriation, and hairballs may accumulate in the gastrointestinal (GI) tract from self-grooming. Reduced productivity and weight loss result from decreased feed intake associated with restlessness. Diagnosis is usually by examination; a hand lens is useful (e.g., otoscope without cone). Interestingly, when a horse is exercised and becomes warm and sweaty, the lice will climb out toward the tip of the hair and are easier to find.[122]

Several treatment approaches exist. Ivermectin at 200 µg/kg every 14 days for two applications is effective for sucking lice but not biting lice. Application of an appropriate topical insecticide to infested animals and to all contact animals at 2-week intervals for two or three treatments is usually curative for both types of lice. Repetition of treatment is necessary to break the louse life cycle because eggs are not killed by insecticides and will hatch despite therapy. Effective topical agents include pyrethroids, permethrins, selenium sulfide, imidacloprid, phoxim, and fipronil.[122] Appropriate attention should be paid to withdrawal times in food animals. Cleaning of fomites such as blankets, brushes, and rope halters is probably indicated, although lice do not live long off the host.

40.33 TROMBICULIDIASIS

Trombiculidiasis is caused by the larval stages of mites commonly known as "harvest mites" or "chiggers." The most common species affecting large animals are *Eutrombicula alfreddugesi* and *Neotrombicula autumnalis*. The

adults and nymphs are free living. The larvae feed on mammalian hosts, secreting substances in their saliva that hydrolyze the epidermis and allow extraction of tissue fluids. The individual larval stage is short, but the infestation may be ongoing with the acquisition of new larvae from the environment. In the Northern Hemisphere, *E. alfreddugesi* is active from late spring through early fall, whereas *N. autumnalis* is more common in the late summer to midfall. The mites may be found in wooded areas, grass, and hay.[122,123]

The clinical signs of trombiculidiasis are crusts and papules, especially on the face, neck, and extremities. Pruritus is variable.[123] Diagnosis may be made early in the course of infestation by careful inspection (e.g., hand lens) and finding the minute, red-orange larvae in the center of a papule. The six-legged larvae have round bodies and may be identified specifically on skin scrapings or acetate tape preparations.[122] Although the larvae only remain on the animal host for several days, clinical signs may persist longer. Thus, trombiculidiasis should be suspected even in the absence of mites in an animal with appropriate signs in the summer and fall.

The disorder is in theory self-limiting because of the short time of attachment of the parasite. However, if the pruritus is severe, corticosteroid administration is indicated.[122] Various products have been used on the horse to eliminate the larvae; 5% lime sulfur, fipronil, and permethrin are generally the safer parasiticides to use.

40.34 MANGE

40.34.1 Psoroptic Mange

Psoroptic mange has been recognized in horses, cattle, sheep, and goats (and rabbits). The host specificity of *Psoroptes equi, P. ovis, P. natalensis,* and *P. cuniculi* is controversial; two recent reports state that the mites are all genetically homogenous with little or no host specificity,[122,124] whereas another report documents an inability to transfer *Psoroptes ovis* to goats.[125] The mites do not affect people. Psoroptic mange is common in cattle but has been eradicated from horses and sheep in the United States; it is still a concern for sheep production in the United Kingdom and elsewhere in the world. The mites have a 2-week life cycle on their host but can live away from the host for up to 3 weeks. *Psoroptes* mites live on the surface of the epidermis and do not burrow. Symptomatic infestation tends to be more prevalent during the cooler months.

The hallmark of infestation in all species is pruritus. In cattle, crusted papular lesions are typically first apparent on the withers but then generalize, resulting in weight loss, secondary infections, and decreased production.[126] Horses develop papules, crusts, and alopecia most often at the base of the mane, tail, ears, and intermandibular area, with subsequent spreading to the trunk.[122] An otitis externa may be present, seemingly with *Psoroptes cuniculi*.[122] In sheep, typical lesions include papules and crusts in wooled areas, and secondary infection with *Staphylococcus aureus* may occur.[127] The intense pruritus can be debilitating. Certain sheep breeds (e.g., merino) are more susceptible to infestation than others.[125] The immune response in sheep has been extensively studied, with early innate and longer-term adaptive cutaneous immunoinflammatory responses as well as mite antigen—directed IgE being reported.[126] Goats usually have lesions restricted to the ears, although infestation and symptoms may spread to the neck and body.[29]

Diagnosis is based on demonstrating mites in skin scrapings and ear swabs from affected animals. Psoroptic mites are recognized by their round bodies and long, segmented pedicles.[29]

A number of topical insecticides have been recommended for treatment and should be applied to all affected and contact animals according to the manufacturer's guidelines. These include deltamethrin, coumaphos, diazinon, malathion, toxaphene, and lime sulfur.[29,123,128] The contaminated environment should also be treated. Ivermectin, doramectin, and moxidectin have been used for *Psoroptes* species in large animals at 0.2 mg/kg subcutaneously (SC),[123,129,130] but treatment does not eliminate live mites from all animals. It has been recommended that *P. ovis*–infested cattle be isolated for a minimum of 14 days after treatment to prevent transmission to susceptible contact cattle.[130] *Psoroptes*-infested ears in horses should not be treated topically because of the resulting discomfort; reliance is on systemic treatment. Psoroptic mange is a reportable disease in the United States.

40.34.2 Chorioptic Mange

Chorioptic mange, also known as leg mange, is common in cattle and sheep, uncommon in goats, and seen with variable frequency in horses depending on geographic area. Draft horses may be more susceptible than other breeds. *Chorioptes* species are relatively host specific and include *C. bovis*, *C. texanus*, *C. ovis*, *C. equi,* and *C. capre*.[29,123,131] The mites do not penetrate the epidermis[123] and do not affect humans.[130] They have a life cycle that spans 2 to 3 weeks and can live off the host for only a few days.[29]

This disease is variably pruritic, more so in ruminants than horses, and less so than infestations with *Psoroptes* or *Sarcoptes* mites. Lesions consisting of papules, erythema, scaling, crusting, ulceration, and alopecia result from self-trauma. In cattle the lower aspects of the hindlimbs, the perineum (particularly the perianal fossa), tail, and scrotum are usually affected. Sheep typically demonstrate involvement of the lower limbs and scrotum. Goats have involvement of the lower limbs. Horses typically have lesions on the pasterns, although the ventral abdomen may become involved in severe cases. In all species, infestation can become generalized.[122,123,130]

Mites are often numerous and readily demonstrated with skin scrapings. Cattle may be asymptomatic.[130] Chorioptic mange will respond to treatments described for psoroptic mange, although ivermectin and related compounds are more effective in ruminants than horses; in horses, lime sulfur or fipronil applied once weekly for at least 1 month is recommended.[122,132,133] A recent study in horses showed efficacy using a single dose of moxidectin 2% oral gel (Equest, Fort Dodge, IA) at the manufacturer's recommended therapeutic dose of 0.4 mg/kg body weight.[133a] Chorioptic mange is a reportable disease in the United States.

40.34.3 Sarcoptic Mange

Sarcoptic mange is an uncommon, contagious disease of horses, cattle, sheep, and goats. The etiologic agent is *Sarcoptes scabiei;* several subspecies are relatively host specific but can be transmitted to humans. The mite burrows into the epidermis, where the egg is deposited, and its life cycle is complete in 10 to 17 days. Transmission is usually by direct contact, but the mite has a variable survival time off the host; therefore, environmental and fomite transmission is possible.[122,123]

The clinical signs are all referable to the severe pruritus caused by the mite. Lesions include papules, scaling, crusting, ulceration, and alopecia. The head (especially the ears) and neck are usually the initial areas of involvement, although lesions become generalized.[29,122,123] Horses in areas frequented by infected wild foxes may have lesions affecting the legs and the ventral abdomen.[122] Dairy cattle may have an associated udder cleft

dermatitis.[134] Sheep tend to have initial involvement of the nonwool areas. The ears should always be scraped for mites; the mite is identified by its rounded body, terminal anus, short legs, and long unsegmented pedicles.[29,122,123]

Because mites may be present only in small numbers, negative skin scrapings do not rule out the disease. Diagnosis should be based on clinical suspicion and response to therapy.[7,29,122,123]

Topical acaricides have been recommended for treatment and are applied to all affected and contact animals at 10- to 14-day intervals for four to six treatments. These include lindane, coumaphos, diazinon, malathion, toxaphene, and lime sulfur.[29,122,123] Ivermectin, 0.2 mg/kg at 2-week intervals for two to four injections (ruminants) or orally (horses), has been shown to be effective, as has injectable moxidectin and topical doramectin. The contaminated environment should also be treated. It is recommended that the state regulatory agency for livestock disease control be consulted for methods of treatment and products to use because sarcoptic mange is a reportable disease.

40.34.4 Demodectic Mange

Demodectic mange is a rare disorder, although it has been recognized in all the large domestic species. The mites live in the hair follicles and in the sebaceous and sweat glands and are host specific. They are not contagious between members of the same species, but *Demodex* species are presumably transmitted from mother to offspring during the first few days of life by direct contact with the dam. Little else is known regarding the life cycle of the mite.[122,123] Two species of *Demodex* are recognized in the horse.[7,122] *Demodex caballi* is a normal inhabitant of the pilosebaceous apparatus of the eyelids and muzzle and may be found in skin scrapings of these areas on horses in the absence of skin lesions. *Demodex equi* inhabits the pilosebaceous apparatus of the remainder of the body and is the species found on horses that has been associated with disease. The species found on cattle, sheep, and goats are *Demodex bovis, D. ovis,* and *D. caprae,* respectively.[29,122,123,130]

Clinical signs are variable, depending on the species affected. The disease is quite rare in horses, which may develop alopecia of the head and trunk; I have seen one case of concurrent demodicosis and chorioptic mange on the legs of a draft horse. Underlying pituitary dysfunction of the pars intermedia has been seen in some horses.[122] Pruritus and secondary pyoderma are variable. Goats and cattle usually develop nodular lesions that involve the face, shoulder, and neck.[135,136] In goats the nodular contents are white and caseous; microscopic examination for mites differentiates the lesions from *Corynebacterium pseudotuberculosis*.[136] Sheep tend to develop periocular nodular lesions.

Diagnosis is based on recognizing mites with microscopic examination of skin scrapings or exudates obtained from nodular lesions. The mites are elongated and have short, stubby legs.[29,122,123]

No treatment has proved to be consistently effective in large animals, although relatively few case reports exist in the literature. Amitraz has not been successful in the treatment of caprine demodicosis.[136] Horses sprayed with 0.025% amitraz developed somnolence, depression, ataxia, muscular weakness, and progressive large intestinal impaction, suggesting that amitraz is contraindicated in equids.[137] Daily ivermectin has been suggested as a successful treatment for equine demodicosis, but dosages have not been codified. Oral ivermectin (0.67 mg/kg once weekly for 12 weeks) and pour-on eprinomectin (0.5 mg/kg) each successfully treated one goat with generalized demodicosis.[138]

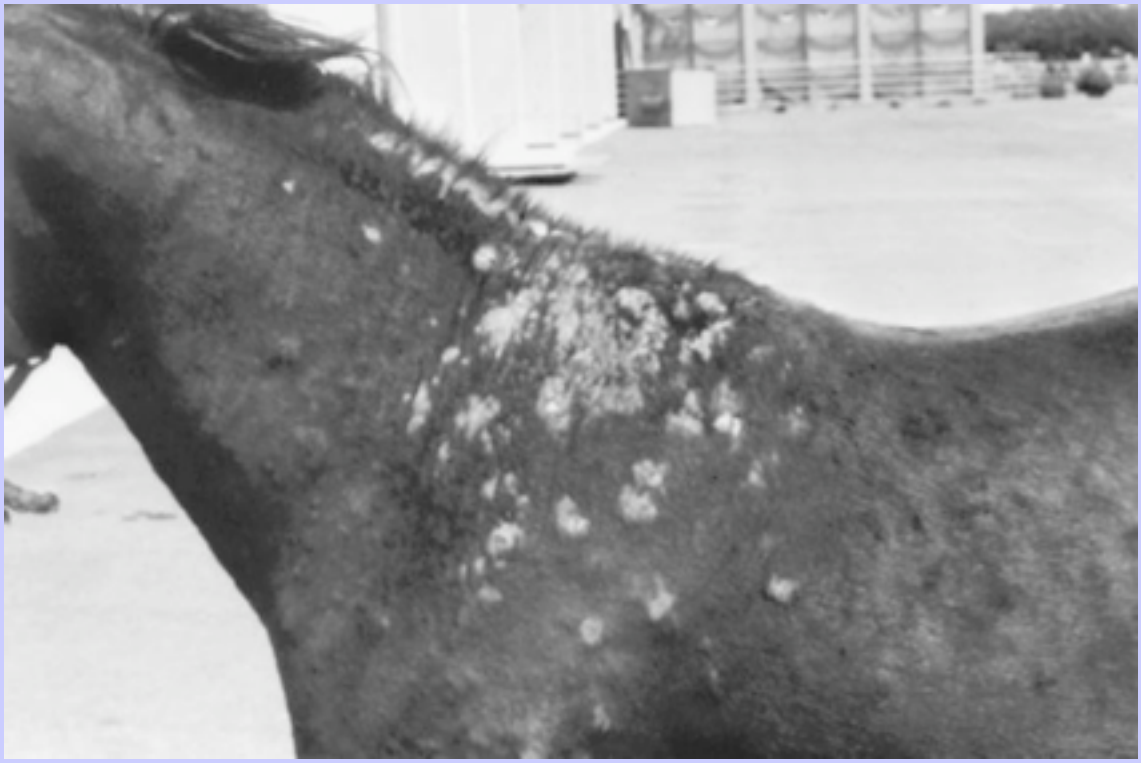
40.35 *CULICOIDES* HYPERSENSITIVITY

The females of various *Culicoides* fly species ("no-see-ums," "punkies") may feed either on the dorsal or the ventral surface of the horse, affecting the mane, saddle, and rump or causing a ventral midline dermatitis in a diffuse pattern. Alopecia, papules, crusts, and erythema may all be present (Fig. 40-12). The insects induce a hypersensitivity response through salivary antigens; this condition is termed *Culicoides* hypersensitivity (Queensland itch, sweet itch) and is recognized in various areas of the world. Evidence indicates a hereditary predisposition to develop the hypersensitivity. Histopathology of lesions frequently reflects a hypersensitivity response.[139] Although many species of *Culicoides* exist, the two most commonly suspected of causing the allergic response are *C. variipennis* and *C. nubeculosus*.

Recent studies have attempted to define the nature of the hypersensitivity response. One study found serum antibodies to *Culicoides* salivary glands in both healthy horses exposed to *Culicoides* bites and in horses with insect "dermal" hypersensitivity.[140] In contrast, no antibodies were detected in serum from native Icelandic horses which had not been exposed to *Culicoides*. Anti—salivary gland immunoglobulin G (IgG) antibodies were detected in both groups of horses, whereas IgE antibodies were only detected in clinically affected horses.[140] A more recent study compared two groups of affected Icelandic horses: those born in Iceland (no previous exposure to *Culicoides*) and transported to Europe, where they were then exposed to the flies, and those born in mainland Europe. The former had IgE and IgG antibodies to a greater number of the insects' salivary proteins.[141] Another study found significantly more IgE-bearing cells in the dermis and epidermis of acute and chronic lesions than in skin biopsies from healthy horses.[142] Further evidence for a hypersensitivity response was demonstrated in a study in which intradermal injection of a *Culicoides* antigen extract induced T lymphocyte and eosinophil accumulation in the skin of affected horses.[143] Other studies have supported the immunologic nature of this disease.[144–148]

The hallmark of disease is pruritus. Although no gender predisposition has been noted, Icelandic horses may have a higher incidence of allergic reactions to the *Culicoides* insects than other breeds. The disease is uncommon in horses under 1 year of age, with an onset usually between 2 and 4 years. *Culicoides* hypersensitivity may be seasonal, at least during the first few years of life, in temperate climates. Diagnosis is primarily by clinical signs. *Culicoides* antigens (commercially available in the United States by Greer, Lenoir, NC) seem useful in both diagnosis and treatment,[149,150] but this needs to be documented in large case studies.

Fig. 40-12 Severe *Culicoides* hypersensitivity in a horse, showing typical distribution of withers, shoulders, and head (not visible).



Therapy is aimed at insect control, especially the following:

1 Stabling horses at sunrise and sunset, peak *Culicoides* feeding hours.

2 Ultrafine setting or screens placed in windows (60 squares to the square inch).

3 Fly control, especially keeping horses away from standing water and using permethrin repellents, usually 2% permethrin sprays. Frequently, sprays must be applied more often than the label recommends (i.e., daily, at least at first). I have had some success using a nonpesticide "herbal" spray or roll-on (MedZone Vet Shield & Sheen, Sun City, AZ).

4 Overhead or stall fans (drafts interfere with insects' flight).

5 "Dresses" that physically obstruct the insects from reaching the skin.

6 Hyposensitization is controversial; success may vary with the presence of an adjuvant, or the actual antigen used.

7 Oral prednisolone to manage the pruritus.

40.36 VENTRAL MIDLINE DERMATITIS OF HORSES

This is a reaction pattern in horses to ectoparasites, and not necessarily specific for any one arthropod. *Culicoides* hypersensitivity, *Onchocerca cervicalis* infestation, and black flies (Simuliidae) may cause generalized ventral midline dermatitis (VMD), whereas horn flies *(Haematobia irritans)* cause a focal dermatitis. Severe chorioptic mange may also involve the ventral midline. In all cases, the lesions have variable alopecia, pruritus, and crusts. Treatment is based on eliminating or repelling the causative organism.

40.37 OTHER FLYING INSECTS

Stable flies *(Stomoxys calcitrans),* black flies (Simuliidae), horn flies *(Haematobia irritans),* horse flies (*Tabanus* and *Hybomitra* species), deer flies (*Chrysops* species), house flies *(Musca domestica),* face flies *(Musca autumnalis),* and mosquitos are commonly associated with irritant and allergic skin disease, as well as being vectors of many parasites. They must be controlled by limiting breeding areas and by repellents; 2% permethrins are often used. It is important to remember the relationship of these various flies to the environments they favor or require for breeding and when they feed, as follows:

Horse flies, deer flies	Vegetation and water	Daytime feeders
Horn flies	Cattle	Daytime feeders
Stable flies	Manure/decaying bedding	Daytime feeders
Black flies	Running water	Morning and evening
Culicoides	Standing water, manure/decaying vegetation	Twilight to dawn
Mosquitoes	Water	Dusk to 2 hours after sunset

40.38 SCREWWORM INFESTATION

Screwworm flies cause primary myiasis; the species of importance in the Americas is *Cochliomyia hominivorax (Callitroga americana)*. The fly was formerly found throughout the American tropics and subtropics from the southern United States to northern Chile.[151,152] It is no longer found in the United States or Mexico as a result of state, federal, and international eradication efforts.[153]

1323

1324

The adult fly is about three times the size of a house fly, with a metallic bluish or blue-green color.[151,153] Females are attracted to fresh wounds (castration, dehorning, branding and shearing sites), abraded body orifices, areas soiled by discharges or excretions, and navels of newborns. They lay batches of 150 to 500 white eggs on the margin of damaged tissue in rows that overlap like shingles. Eggs hatch within 24 hours, and the larvae begin to feed in a head-downward position. Larvae are obligate parasites that require living tissue as feedstuff. They cannot develop in carrion. Larval development continues for 4 to 10 days, and at the time of their maturation, they may have created a cavity 10 to 12 cm (4 to 5 inches) in diameter.[152] Mature larvae are about 2 cm in length, pink in color, pointed anteriorly, and blunt posteriorly. The larvae then drop to the soil and pupate. The life cycle averages about 21 days and is favored by hot, humid weather.

Screwworms do not have a dormant stage in their life cycle and cannot overwinter in cold climates.[151] Thus the susceptible stage of development is the pupae, which will not survive soil temperatures below 15° C (59° F). The feeding larvae burrow deeply, creating a cavernous lesion characterized by liquefaction necrosis, profuse brownish exudate, and an objectionable odor. The syndrome is self-perpetuating in that wounds infested by screwworm larvae become increasingly attractive to gravid females. The end result is often death of the host as a result of secondary bacterial infection, toxemia, and fluid loss.[152]

Treatment of wounds requires clipping and cleansing, as well as destroying all larvae. Dressings containing larvicides and antiseptics should be applied. Preparations containing lindane or organophosphates have been used in an ointment or gel base. The treatment is repeated twice weekly. When large numbers of animals are affected, a 0.25% solution of coumaphos, chlorfenvinphos, or fenchlorphos may be applied to herds with a power sprayer. Calves may become ill from the spray; thus applications should be restricted to the ventral abdomen.[152] More recently, the curative efficacy of fipronil 1% against *C. hominivorax* larvae infestation in castration wounds was 100%.[154] Even more impressive, doramectin as a prophylactic treatment was 100% effective in prevention of *C. hominivorax* infestations.[155]

Control of screwworm flies in the United States has been achieved largely through the release of sterile males, because of the single mating tendency of the female fly. The eradication program has proceeded through Mexico south to the twenty-first-degree parallel.[151] Screwworm myiasis is a reportable disease in the United States, and suspect larvae should be preserved in 70% alcohol for positive identification.[156]

40.39 BLOW FLY STRIKE (FLEECEWORMS, WOOLMAGGOTS, SECONDARY SCREWWORMS)

Blow flies are found throughout the Western Hemisphere. The species of importance include *Cochliomyia macellaria* (secondary screwworm), *Phaenicia sericata* (green bottle fly), and *Phormia regina* (black blow fly). The flies tend to be most common in the warmer regions, with the exception of *P. regina,* which is widespread throughout the cooler parts of North America and Europe.[151] Blow flies cause serious loss of sheep and wool in many countries.[153] Female flies are attracted to decaying animal matter, such as wounds infested by primary screwworms, infected sores, carcasses, and fleeces that are dampened with feces, urine, or bloody fluids.[151] They lay eggs in batches of up to 300, which hatch within hours. The larvae feed on necrotic tissue but may invade healthy tissue. Larvae develop for 3 to 5 days and, when fully mature, are white and 6 to 12 mm in length. The larvae then drop to the ground for pupation. As soil temperatures fall, larvae fail to pupate and may overwinter until the following spring. The entire life cycle is generally complete in 2 to 4 weeks under ideal conditions of warm temperatures and high humidity.[152]

Unlike primary screwworms that feed in pocket-like aggregations, secondary screwworms tend to be dispersed throughout the infested tissue. In wool infestation the larvae may remain on the skin surface, feeding on the decomposing wool, or may penetrate the skin through small abrasions. The most common site of involvement is the breech. Infested tissue attracts more ovipositing females, and thus the syndrome is perpetuated.[151] Affected sheep are restless and do not feed. They move with their heads close to the ground, bite or kick at their wounds, and continually wriggle their tails. Affected wool is moist and brown with an obvious odor. Animals may become systemically ill and die.[156]

Treatment of individual wounds is as described for screwworms. Control involves management practices that decrease the incidence of wounds or skin irritations. Sheep are often clipped below the tail and between the hindlimbs ("crutched"), where wool is likely to become saturated with urine or feces. Castration, shearing, docking, and lambing are avoided during the summer season.[151]

40.40 CUTANEOUS ONCHOCERCIASIS

40.40.1 Definition and Etiology

Cutaneous onchocerciasis in horses is a common filarial dermatitis with a worldwide distribution. Its incidence in the United States has decreased dramatically since the introduction of ivermectin for routine deworming. In a recent report from South America, *Onchocerca cervicalis* microfilariae were detected in midventral skin biopsy samples in 215 (17.9%) of 1200 horses examined, and the adult worms were recovered from 200 (16.6%) ligamentum nuchae from the same animals.[157]

The disease is caused by the microfilaria of *O. cervicalis* and is seen primarily in adult horses.[158,159] Adults typically are found coiled in the funicular part of the ligamentum nuchae, where they produce calcified nodules. Viviparous females may live for up to 5 years and produce large numbers of microfilariae that migrate through connective tissues to the superficial layers of the dermis. Preferential areas of microfilarial localization include the ventral midline, lower eyelid, and lateral limbus of the eye.[158] The infection is transmitted by *Culicoides,* which act as an intermediate host. The larvae are ingested by the vector and undergo development into the third-stage larvae (L_3) in approximately 2 weeks. The L_3 larvae enter the animal host through lesions created by the feeding vector.[33] Many horses are infected with the parasite without demonstrating clinical disease.[33,158]

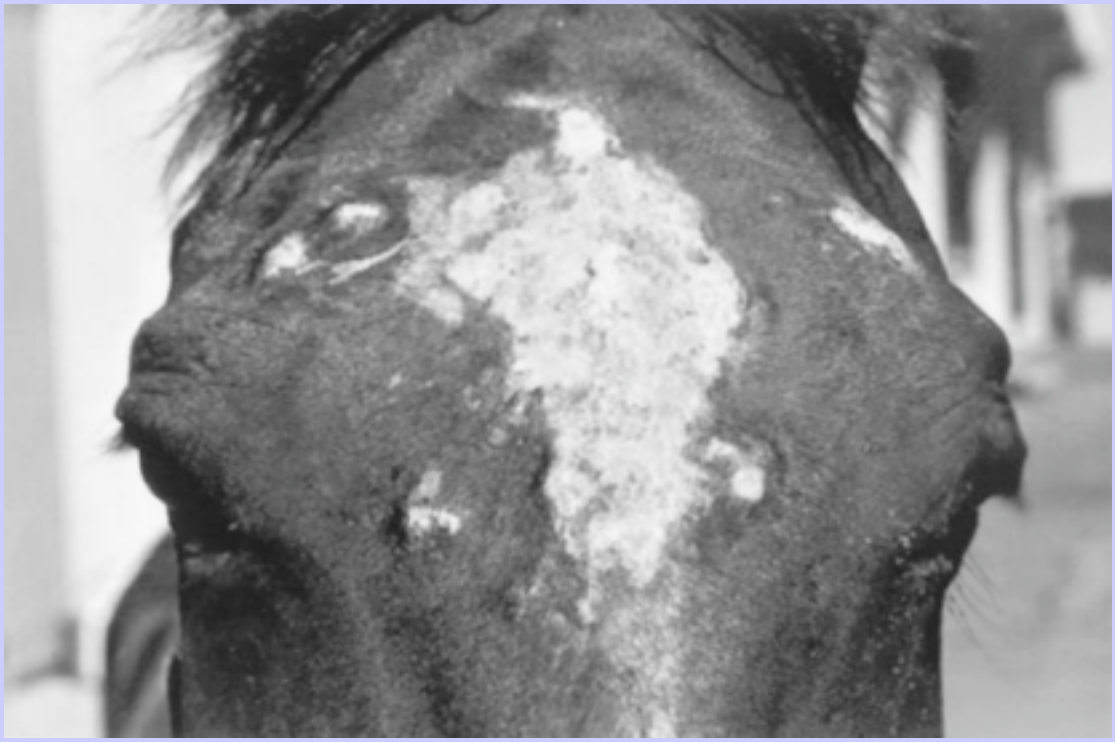
40.40.2 Pathophysiology

Pathogenesis is believed to involve a hypersensitivity reaction to antigens released by dying microfilariae.[33,158] This theory has support because not all infected horses demonstrate disease, neither the presence nor the severity of the dermatitis is correlated with the number of organisms present, and treatment with filaricides often causes a temporary exacerbation of clinical signs.

40.40.3 Clinical Signs

Clinical signs occur most often in older horses and can include both ocular and cutaneous lesions.[33,158] Ocular lesions include uveitis, conjunctivitis, keratitis, and depigmentation of the lateral limbus.[160] Cutaneous lesions include diffuse or patchy alopecia, erythema, and scaling. Focal cutaneous depigmentation is common. Lesions tend to occur in regions where microfilariae are typically present in highest concentrations, such as the ventral midline, face (Fig. 40-13), base of the mane, anteromedial proximal forelimbs, and anterior pectoral region. An inflammatory, alopecic, or hyperpigmented area in the center of the forehead is highly suggestive of the disorder.[33] The dermatitis is generally reported as being nonseasonal and nonpruritic.[33,161]

Fig. 40-13 Cutaneous onchocerciasis in a horse.



40.40.4 Diagnosis and Histopathology

Because many normal horses have microfilariae without disease, the finding of microfilariae does not prove that they are the cause of the cutaneous lesions. In addition, because microfilariae tend to "nest" in the dermis, there is a tremendous difference in the number of microfilariae recovered from adjacent skin samples.[158,162] Thus, although the absence of microfilariae makes cutaneous onchocerciasis unlikely, it does not definitively exclude it as a diagnosis. Differential diagnoses should include ventral midline dermatitis caused by the horn fly *Haematobia irritans,* hypersensitivity reaction to *Culicoides,* dermatophytosis, and infestation with mange mites.

Ultimately, diagnosis should be based on history, supportive clinical findings, exclusion of other differential diagnoses, and most importantly, response to treatment.

A positive *Onchocerca* microfilarial saline preparation demonstrates slender, delicate microfilariae that are approximately 8 × 220 µm. Typical histopathologic changes include an eosinophilic and lymphocytic perivascular dermatitis, a finding that is nonspecific and common to many other equine parasitic dermatoses (see Chapter 11). Aggregations of microfilariae may be found in the superficial dermis or perifollicular region.[33,158,162]

40.40.5 Therapy

Ivermectin or moxidectin are the treatments of choice and are administered at 0.2 mg/kg PO.[163,164] Most horses improve within 2 to 3 weeks. Minor adverse reactions, including fever and swelling of the periorbital, facial, and ventral midline regions, may occur in up to 25% of infected horses treated with ivermectin; moxidectin did not cause posttreatment dermal reactions in one study.[164] Severe reactions may benefit from treatment with corticosteroids, but most reactions resolve within 24 to 72 hours. Because there is no effective adulticide, recurrence may be noted as soon as 2 months after therapy. Most animals remain free of clinical signs for 6 to 12 months.[161,163] Re-treatment is recommended at 4-month intervals.

In cattle, onchocerciasis has been caused by the microfilariae of *Onchocerca gutturosa* and *Onchocerca lienalis* and in Africa, *Onchocerca ochengi*.[165,166] Flies of Simuliidae are the vectors. The disease causes nodules and crust on the skin, including the teats; adult worms surrounded by neutrophils were detected free in the teat canal.[166] Ivermectin and moxidectin are effective treatments.[165]

40.41 STEPHANOFILARIASIS

Cutaneous stephanofilariasis is a filarial dermatitis of cattle. The disease is caused by organisms of the genus *Stephanofilaria* and has been observed in cattle in many countries.[167,168] Within the United States the disease is most prevalent in the western and southwestern regions, where it is caused by *Stephanofilaria stilesi*.[156,159,169] Adults and microfilariae inhabit the epidermis. The parasite is transmitted by the female horn fly *(Haematobia irritans)* when it feeds on lesions on the ventral midline.[159] The microfilariae are ingested and develop to infective L_3 larvae in 2 to 3 weeks. The L_3 stage is introduced into the animal host on subsequent feedings.[169]

Clinical signs of cutaneous stephanofilariasis include a ventral midline dermatitis initially associated with a papular eruption. The scrotum may also be affected.[170] The lesions progress to nodules, alopecia, and crusted ulcers. There may be mild pruritus.[152] Diagnosis is based on history and appropriate clinical signs, excluding differential diagnosis and demonstration of the nematode. Biopsies may be taken as described for equine onchocerciasis, or the crust can be removed from an acute lesion and deep skin scrapings performed to recover the parasite. The tissues should be minced in isotonic saline and then examined microscopically. Multiple skin scrapings may be required to demonstrate the parasite. Either adults or microfilariae may be found. The adult male is about 3 mm in length and the adult female 6 mm in length.[167] Microfilariae are 50 μm in length.[167] Characteristic histopathologic findings include a perivascular dermatitis associated with an eosinophilia. Microfilariae may be noted in the dermis, and adults in epithelial-lined cysts at the base of the hair follicles, although both may be difficult to find.[167]

There is no approved treatment for stephanofilariasis, although approved topical organophosphates have been suggested.[159] Some authors have not recommended treatment because clinical signs are relatively mild in many animals.[169] Cattle with zebu ancestry may be more resistant.[168]

40.42 HYPODERMA (WARBLES)

40.42.1 Definition and Etiology

Infestation with the larvae of *Hypoderma* species is a common and serious economic problem in cattle and is recognized sporadically in horses that are pastured near cattle. Occurrences have also been reported in sheep, goats, and humans.[171] Warble flies are present in the Northern Hemisphere between 25 and 60 degrees latitude in more than 50 countries of North America, Europe, Africa, and Asia. *Hypoderma* species are not established south of the equator.[152,171] The U.S. cattle industry loses millions of dollars annually because of cattle grubs.

Two species of *Hypoderma* parasitize cattle: *H. bovis* and *H. lineatum*. The latter prefers warmer climates and is the only *Hypoderma* species present in the southern United States. Each of the species occurs in the northern United States and in Canada.[152] *H. lineatum* and *H. bovis* have very similar life cycles, but the stages of *H. lineatum* tend to occur 3 to 8 weeks earlier than those of *H. bovis*. Timing of the life cycle also varies with local geographic and climatic factors.[152,171]

1325

1326

The adult flies are beelike in appearance, covered with dense chin bristles (hair), 12 to 188 mm in length, and have nonfunctional mouthparts.[172] They have a short lifespan, only 1 week. Adult flies are active in the spring to early summer, with *H. lineatum* appearing 3 to 4 weeks before *H. bovis*. Female *H. lineatum* flies deposit eggs on the hairs of the legs or lower body, whereas *H. bovis* tends to deposit eggs on the rump or upper parts of the hindlimbs. Total egg production by a single female has been estimated to range from 500 to 800.[172] The eggs hatch in 3 to 7 days, after which the larvae penetrate the skin and begin their migration through the connective tissues. *H. lineatum* larvae migrate to the subcutaneous connective tissues of the esophageal wall, whereas *H. bovis* larvae migrate toward the spinal canal. The first-stage (L_1) larvae remain in this location for 2 to 4 months, during autumn and early winter. Between January and February the larvae begin a final migration through the connective tissues to the subdermal tissue of the back of the host, where they form a breathing hole through the skin. Cysts (warbles) develop around L_1 larvae. Within the cyst the larvae undergo two molts over a 4- to 6-week period. The L_3 larvae (grub) emerge from the breathing pore, fall to the ground, and pupate. Adult flies emerge from the pupae in 1 to 3 months, and emergent adults are ready to mate almost immediately.[172,156] The life cycle is complete in 1 year. Most larvae fail to reach normal size and complete their life cycle in the horse.[171,172]

40.42.2 Clinical signs

40.42.2.1 CATTLE

During the spring and summer when adult flies are active, “fly worry” may be a serious problem. Cattle exhibit a stampeding behavior called “gadding” when chased by ovipositing females, even though the flies do not bite or sting. This fear reaction results in self-injury and decreased feeding and milk production.[172] Diagnosis of warble flies in goats by ELISA has been reported, but it is not known whether this is applicable to cattle.[173]

Clinical lesions are not usually observed in association with migration of L_1 larvae unless the larvae die along the migratory path.[171] Lesions that have been associated with infestation of L_1 larvae of *H. bovis* include fat necrosis and inflammation of the connective tissues surrounding the spinal canal. Secondary periostitis, osteomyelitis, and rarely paralysis or other nervous disorders may occur. Similarly, infestation with L_1 larvae of *H. lineatum* in the submucosa of the esophagus may cause inflammation and edema in the surrounding tissues. Swallowing and eructation may be hindered, resulting in bloat and subsequent respiratory failure.[171]

Lesions most often observed with *Hypoderma* infestation are attributed to L_3 larvae. Warbles occur along the back from the shoulders to the tailhead and from the dorsal midline to a point about one-third the distance down the sides. The lesions may be firm to fluctuant, raised, and painful to the touch. They measure approximately 3 cm in diameter and contain a breathing pore that usually exudes a yellowish serum. Excisional biopsy of a nodular lesion reveals the larvae within a cystlike structure that contains yellow fluid. The surrounding tissue is necrotic. Secondary infection of the cysts can result in large, suppurating abscesses. The number of warbles in an infested animal may range from 1 to 300. Infestations are most serious in younger animals and become progressively less severe with age. Emergence of the grub results in healing, although carcasses retain evidence of infestation and are devalued at slaughter.[152,171]

40.42.2.2 HORSES

Most horses have only one or two grubs, but heavy infestation is present in rare cases. Lesions associated with L_3 larvae include small, nodular swellings that develop dorsally and frequently in the region of the withers. Most lesions have a breathing pore.[156] Differential diagnosis is most often nodular collagenolytic granuloma (nodular necrobiosis), but mastocytoma, sterile nodular panniculitis, and amyloidosis should also be considered. Posterior paralysis associated with involvement of the spinal cord has been reported in both horses and cattle.[171]

The season, location of the lesion(s), and presence of a breathing pore are usually diagnostic. Larvae can be recovered by enlarging the breathing pore with a scalpel and extracting the grub.

40.42.3 Therapy

When small numbers of cattle are affected with just a few grubs, manual removal of the grubs is possible by simply enlarging the breathing pore. This is usually the preferred treatment in horses as well, if only one or two lesions are present. Care must be taken to remove the larvae in their entirety because breaking the larvae and rupturing the cyst during removal can result in a severe systemic reaction.[152,171]

Systemic insecticides are the only means of eliminating the migrating larvae. Organophosphates or the macrocyclic lactones (doramectin, eprinomectin, ivermectin, moxidectin) have been used for this purpose and are applied on the midline of the back.[171,174] Administration of insecticides should be timed to provide treatment in early autumn after all eggs have hatched and larvae are in the early stages of their connective tissue migration. Third-stage larvae are less susceptible to insecticides, and destruction of larvae in later stages of migration increases the risk of serious secondary illness. It is advisable not to administer systemic insecticides later than 8 to 12 weeks before the anticipated first appearance of grubs along the back.[152,171] In the northern United States and Canada, treatment of cattle with systemic insecticides is not recommended from October 1 to

March 1 because this is when *H. bovis* larvae are located in the epidural space and *H. lineatum* larvae reside in the esophagus.[152]

40.43 SHEEP KEDS

The sheep ked, *Melophagus ovinus,* is a wingless fly approximately 6 to 7 mm in diameter with a ticklike appearance. Sheep keds have a worldwide distribution. They primarily parasitize sheep and occasionally goats that are kept under poor management conditions.[152,175]

The entire life cycle is spent on the host. Females live 4 to 5 months, laying 10 to 15 larvae individually that are cemented to the wool or hair. The larvae pupate in 12 hours, and the adult emerges 3 weeks later. Adults feed on blood and do not survive longer than a few days off the host. Transmission is by direct contact, and infestation is more common in the winter months.[152,153,175]

Clinical signs of infestation include pruritus with subsequent self-trauma, wool stains from the flies' fecal material, and in severely parasitized animals, anemia. Multiple firm nodules (cockles) develop as a result of repeated puncture of the skin as the keds feed.[152,153] Infestation results in economic loss from a reduction in dressed carcass weights of lambs, reduced clean dry weight of fleece, wool staining, and reduced value of sheep skins because of nodular defects.[152,175,176] Diagnosis is based on demonstration of the parasite.

Therapy involves shearing all sheep in the affected flock, followed by two topical applications of malathion, diazinon, or coumaphos at 14- to 21-day intervals to kill emerging adults.[152] Because the larvae are attached to the wool or hair some distance above the skin surface, many larvae and pupae are removed by shearing.[153,176] Recently, imidacloprid was found to be effective in killing the parasite.[177] All new animals should be isolated and treated before introduction to prevent reinfestation. A control program includes annual treatment of the entire flock.

1326

1327

40.44 CUTANEOUS HABRONEMIASIS (EQUINE SUMMER SORE)

Habronemiasis ("summer sore") is a granulomatous disease caused by the deposition of *Habronema microstoma*, *Habronema muscae,* or *Draschia megastoma* larvae by flies at the site of wounds or natural body moisture (sheath, eyes).[178,179] The adult parasites normally reside in the stomach, where they cause little tissue reaction, with the exception of *D. megastoma,* which produces gastric nodules of varying sizes near the margo plicatus. Females are viviparous, and larvae are passed in the feces, where they are then ingested by the larvae of flies acting as intermediate hosts. *H. muscae* and *D. megastoma* develop in the house fly, *Musca domestica,* and *H. microstoma* develops in the stable fly, *Stomoxys calcitrans*.[159] The L_3 larvae are then deposited around the horse's mouth and swallowed to pass to the stomach, where they mature to adults. Cutaneous lesions occur when the larvae are deposited in damaged skin or areas of natural body moisture. The larvae cannot penetrate normal healthy skin.[33] In these aberrant locations, they are unable to mature to adults, and the resulting proliferative lesions are thought to represent a hypersensitivity reaction to the dead or dying larvae. In temperate parts of the world, habronemiasis is a seasonal disease, occurring in warm, wet weather.

Arabians, gray horses, and horses with a dilute hair coat seemingly have a predilection for this disease. The medial canthus of the eye, male genitalia, nictitating membrane ("third eyelid"), and distal extremities are the most common parts of the body affected.[178] Lesions consist of ulcers and nodules. Diagnosis is based on clinical

signs, history, and the presence of calcified concretions (sulfur granules) and is confirmed by biopsy. The nodular lesions may take on the gross appearance of neoplasia. Alternatively, the larvae may infest a preexisting tumor, especially squamous cell carcinoma of the male genitalia, and a biopsy is crucial for accurate diagnosis. Characteristic histopathologic findings include granulation tissue with a diffuse infiltration of eosinophils and an ulcerative epithelial surface. The granulation tissue usually contains focal areas of coagulation necrosis surrounded by a dense eosinophilic infiltrate. Cross sections of larvae can often be identified within some of the necrotic foci.[178] Rarely, larvae are found in scrapings from the lesions.[159] Larvae are not always found in the biopsy sections[178]; in these cases, if neoplasia has been ruled out, presumptive treatment for habronemiasis should be performed. Recently, a PCR assay for diagnosing habronemiasis has been developed; this may hold promise in the future for those cases wherein the larvae are not found on biopsy.[179a]

Treatment in the past has been either corticosteroids or organophosphates, topical or systemic. Ivermectin (0.3 mg/kg PO) has been shown to be effective and is considered the treatment of choice by many clinicians. Moxidectin (0.4 mg/kg PO) may also be used. Systemic corticosteroids (e.g., prednisolone, 1 mg/kg once daily for 10 to 14 days, then tapered over 2 weeks) or intralesional or topical corticosteroids often are used because of the hypersensitivity-reaction nature of the disease process. In severe cases, surgical removal or debulking of the lesion should be considered.[179]

Habronemiasis has been seen in horses routinely given ivermectin as part of their deworming program.[179] Prompt removal and disposal of manure and soiled bedding are important to eliminate vector breeding habitats. Insect repellents should be applied to affected horses. Face guards (fly masks) will also prevent infection. In general, the prognosis for resolution of individual lesions is good if the therapeutic goals are achieved.

40.45 TUMORS AND CYSTS

40.45.1 SQUAMOUS CELL CARCINOMA

STEPHEN D. WHITE

40.45.1.1 Definition

Squamous cell carcinomas (SCCs) are tumors composed of squamous epithelial cells. They occur in all domestic species and are the most common bovine ocular tumor (see Chapter 39) and the second most common tumor recognized in the horse.[180] Although their gross appearance may vary, these tumors are usually slightly raised, broad based, and white to pink and have a cobbled or cauliflower-like surface. SCCs frequently occur on the penis and sheath of aged stallions and geldings (see Chapter 43). They also occur on the lips, nose, eyelids, eyes, and ears of horses. SCC often accompanies cutaneous papillomas of the udder and teats in Saanen milk goats, as well as in female Angora goats in South Africa. The ears, base of the horns, and prepuce may also be affected.[181] SCC is reported as being the most common cancer of the ear of sheep; an outbreak primarily affecting the eyelids in 15% to 18 % of a sheep population has been reported.[182] Diagnosis is by biopsy.

The treatment of choice is wide surgical excision.[183,184] Solar elastosis (aggregates of thick, wavy, interwoven elastic fibers, mixed with areas of degenerated collagen), when seen histologically with SCC, may lend a more favorable prognosis after complete surgical removal of lesions.[185] Other treatment

modalities reported as successful include cryosurgery, radiofrequency hyperthermia, and radiation therapy.[186] More recently, topical application of 5-fluorouracil (5-FU) and intralesional cisplatin were shown to be effective in horses with SCC.[187–190] Piroxicam was successful in the long-term control of SCC with metastases in one horse.[191]

40.46 EQUINE SARCOID

ALAIN P. THÉON

40.46.1 Epidemiology and Pathogenesis

The equine sarcoid was first reported in 1936 by Jackson.[192] It is the most common tumor in Equidae (horses, mules, and donkeys) worldwide and accounts for more than 50% of cutaneous tumors.

Sarcoids are locally aggressive, nonregressing, fibroblastic tumors of the dermis and subcutis with a variable proliferative epithelial component. This dual epidermal-dermal involvement is the hallmark of the sarcoid and explains its multiple and evolving clinical appearance. The epidermal component of sarcoid shares features with benign papilloma, and the fibroblastic component is consistent with low-grade fibrosarcoma.[193] These characteristics can lead to an incorrect histologic diagnosis of fibrosarcoma or nerve sheath tumors when the skin is not included in the tissue analyzed.[194]

Despite numerous clinical reports on sarcoids, the clinical and epidemiologic data are still puzzling. The inconsistent and sometimes conflicting data do not support a gender, breed, age, or genetic predisposition or any anatomic predilection.[195] These data reflect in part the frequent lack of histologic confirmation of the disease in reported studies and may represent regional or national variations in the clinical characteristics of sarcoids.

Epidemiologic evidence of a causative agent comes from the fact that age is not a risk factor. Unlike spontaneous tumors, affected horses are likely to have synchronous or metachronous lesions,[195] and sarcoid outbreaks have been reported.[196] It is widely accepted that bovine papillomavirus (BPV) types 1 and 2 are associated with the pathogenesis of sarcoid disease. The presence of viral genetic material is apparently necessary because it is always found in sarcoids, although it is not sufficient to produce the disease. The lesions and surrounding normal cutaneous margins contain detectable sequences of the viral genome, including E5, E6, and occasionally E2.[197,198] Both the epithelial and the fibroblastic component of the tumor contains viral genetic sequences.[199] However, the infecting viral genome sequences are nonproductive for infectious virions, and viral particles have never been detected. Transmission studies of sarcoids have been unsuccessful. Inoculation of sarcoid cell—free extract does not induce warts in cows or sarcoids in unaffected horses.[194] Experimental infection with BPV induces fibropapillomas clinically similar to sarcoids that regress spontaneously with production of antibodies to the virus.[200]

1327 1328

The mode of transmission of sarcoid disease is unknown. It does not occur by casual contact with contaminated fomites or affected horses[201] or by BPV-infected insect bites.[202] The mechanisms of cellular oncogenesis are similar to those of other transforming papillomaviruses. Oncogenesis is associated with genomic integration and expression of the two transforming genes E6 and E7, which respectively bind to cell cycle control gene products, the Rb and p53 proteins.[203]

40.46.2 Biologic Behavior

Clinically, many sarcoids behave initially as benign lesions because they are slow growing, giving the false impression that the lesion is inactive. In addition, sarcoids are frequently classified as biologically "benign" tumors because they do not metastasize to distant organs, and regional metastasis is rare and usually associated with unsuccessful treatments.[204] However, the equine sarcoid is not a benign tumor because it is a progressive disease that invades and destroys surrounding normal tissue, does not regress spontaneously, and recurs predictably after surgical removal.[194,203,205] Early lesions are restricted to the dermis and epidermis, but advanced lesions typically invade the subcutis and may extend through fascia into deeper muscular structures. Considering sarcoids as benign tumors leads to inappropriate management early in the course of the disease and thus to multiple recurrences, resulting in unsatisfactory cosmetic and functional outcomes as well as unnecessary expenses to control the disease.

40.46.3 Clinical Findings and Diagnosis

Sarcoids are recognized as having different clinical manifestations, including occult, verrucous, and nodular clinical types[194] (Fig. 40-14). In addition, approximately one third of affected horses have multiple sarcoids at different clinical stages on diagnosis.[195] The different types represent stages of tumor progression and reflect the relative predominance of the dermal or epidermal component. Lesions with a predominant epidermal component include occult and verrucous sarcoids. *Occult* sarcoids appear as an almost-circular area of alopecia with a gray, scaly surface. *Verrucous* sarcoids may be sessile (flat variety) or pedunculated (warty variety); the skin is thickened with a dry rough surface, with partial or total alopecia. *Nodular* sarcoids, also called *fibroblastic* sarcoids, range in appearance from a dermal or subcutaneous nodule to a large, exophytic mass with a skin surface that eventually ulcerates. The nodular type is locally invasive, destroying adjacent tissues, and may ultimately infiltrate lymphatic vessels and nerve sheaths and disseminate to form regional metastases.[204] Mixed forms represent a transition from one type to another. Other classifications have been proposed, including up to six clinical types with four subtypes.[206] The multiplicity of recognized clinical forms confirms the equivocal and progressive nature of sarcoid disease. A classification, however, must be simple and reflect the biology of the disease to be clinically relevant and have prognostic value. As a result, tumors should be categorized as *indolent* sarcoids, including occult and verrucous types, or *invasive* nodular sarcoids. Invasive sarcoids may result from a sarcomatous progression of an indolent form or may appear de novo.

The polymorphic appearance of sarcoids, the lack of consensus on clinical classification and anatomic distribution, and the long list of differential diagnoses make the clinical diagnosis of sarcoids unreliable. The diagnosis and treatment of sarcoids require a biopsy because they are often overdiagnosed clinically. In a review of 681 horses referred to the Oncology Clinic at the Veterinary Medical Teaching Hospital of the UCD School of Veterinary Medicine for evaluation and treatment of sarcoids from January 1995 to June 2004, 345 cases were presented with a clinical diagnosis of sarcoid without a biopsy, and 31% of these were found to have nonneoplastic dermatologic conditions.[207] After ruling out a nonneoplastic skin condition, any clinically suspicious lesion should be biopsied.[208] As with any tumor, early recognition and treatment of a small lesion are always associated with a better prognosis. It is important to keep in mind that any large and invasive sarcoid associated with a poor prognosis was, earlier in its evolution, an apparently inactive small lesion that was not recognized or was deliberately neglected. There is no contraindication for biopsy of a suspicious skin lesion as long as definitive treatment is instituted immediately after the diagnosis is made. Clinicians should not be concerned about performing a biopsy of a suspected sarcoid because effective treatments are available. As with

any trauma, however, a biopsy can increase proliferation of a previously slow-growing tumor and may accelerate tumor progression. As a result, a biopsy should not be recommended if the owner is not willing to pursue treatment, if needed, because the process of biopsy without subsequent treatment has the same effect on overall prognosis as an unsuccessful attempt at treatment.

40.46.4 Therapy

Because tumor size and previous unsuccessful treatment attempts are the most important prognostic factors,[205,207] early and complete surgical resection is the mainstay of treatment of sarcoids.[208] Failure to eliminate the disease results in regrowth of a tumor that is histologically and biologically more aggressive and requires wider excision than the primary lesion. After surgery, it is critical to submit the resected specimen for histopathologic examination to determine the status of the surgical margins. As a rule, grossly or histologically incomplete resection (i.e., positive or close pathologic margins, <5 mm) must be followed by a re-resection, if possible, or by effective adjuvant treatment. For noninvasive sarcoids resected with pathologic margins greater than 5 mm and invasive sarcoids with margins greater than 1 cm, the risk of recurrence is low, and no further treatment except observation at regular intervals for at least 1 year is recommended. For invasive sarcoids resected with surgical margins between 5 and 10 mm, the risk of recurrence is high, and adjuvant treatment may be recommended, particularly when tumor recurrence may be difficult to manage because of unfavorable anatomic location. Access to molecular techniques (PCR and TaqMan PCR) designed to detect BPV E5 or E6 in pathologic margins will help assess the risk of recurrence and determine the need for adjuvant treatment.[209]

C

Among the nonsurgical treatments, interstitial radiation therapy and intralesional chemotherapy with cisplatin have well-documented efficacy against biopsy-confirmed sarcoids of all clinical types in any location.[210,211] Compared with radiation therapy, intratumoral chemotherapy with cisplatin is as effective, but without long-term side effects, and it does not require a special license. Although several antineoplastic drugs[212–215] and drug formulations[205,207,213,214,216] for intralesional chemotherapy have been evaluated, a crystal suspension of cisplatin in a sesame seed oil and Sorbitan monooleate (Span 80) emulsion has been shown most effective. (Native protein [i.e., the patient's own serum] preparations are proscribed because of their strong binding to cisplatin.[217]) When all stages and clinical types were combined, the cure rate after treatment with intratumoral cisplatin therapy used alone or as an adjuvant to surgery has been reported to be as high as 96%.[207] Treatment includes a series of four intralesional doses of cisplatin (~1 mg/cm^3 tissue) given at 2-week intervals. Generic cisplatin is widely available and inexpensive. Treatments are done on an outpatient basis, and the methods of administration and safety precautions have been described.[214]

Nonspecific immunotherapy using bacille Calmette-Guérin (BCG) cell wall derivatives* administered intralesionally[211] has been shown to be effective only for periocular sarcoids.[205,218,219] The number of treatments depends on the rate of tumor regression, and the treatment schedule is dependent on normal tissue toxicity; most sarcoids require 2 to 9 treatments over several weeks.[205]

Encouraging results have been reported with imiquimod, a biologic response modifier, used topically.† The ointment is recommended for the treatment of viral warts and basal cell carcinomas in people. It is applied as a thin layer to the tumor surface three times a week on nonconsecutive days, up to 32 weeks until resolution.[220] The reported 60% response rate suggests that topical imiquimod may be a therapeutic option for specific equine sarcoids. However, the data must be confirmed in a larger series of horses with sarcoids and after adequate long-term follow-up.

1329
1330

Topical applications of escharotics with zinc chloride—based caustic ointments* or 5-FU cream† are used empirically for treatment of sarcoids. Unfortunately, no scientific data have been published documenting treatment efficacy against actual equine sarcoids. As a result, no information on treatment protocol, efficacy, prognosis, or toxicity is available.

40.47 MASTOCYTOSIS

STEPHEN D. WHITE

In horses, mastocytosis (mast cell tumors, mastocytomas) occur in animals 1 to 18 years old (average, 9 years), with no breed predilection. A predilection for males has been proposed but is not always sustained.[221,222] In addition, multiple mast cell tumors resembling urticaria pigmentosa of humans may occur in newborn foals; these spontaneously appear and regress.[222,223]

Equine mastocytosis is usually solitary and occurs most often on the head and trunk. Lesions are 0.5 to 20 cm in diameter, well to poorly circumscribed, firm to fluctuant, dermal or subcutaneous, and may or may not be alopecic, ulcerated, and hyperpigmented. Lesions on the legs tend to be very firm and immovable.

Histology may vary from sheets of mast cells with few eosinophils (presumably early lesions) to sections showing both sheets of mast cells with numerous eosinophils and collagen degranulation. Ultrastructural features are similar to those noted in mastocytomas of other species.[224]

Clinically, most mast cell tumors in horses do not recur after being excised (22 of 25 in one study).[224] In one anecdotal case of metastasis from a tumor on the muzzle to regional lymph nodes, the tumor and the nodes were removed, and the horse was clinically sound 3 years later. There is some debate as to whether equine mastocytomas are benign neoplasias or focal dysplasias of mast cells.

Mastocytomas are uncommon in cattle but typically occur in young calves.[225,226] One report describes a cutaneous mast cell tumor in a kid goat.[227] Although equine mastocytomas are almost always benign, mastocytosis in cattle may be malignant or benign and therefore carry a more guarded prognosis.

40.48 MELANOMA

STEPHEN D. WHITE

40.48.1 Equine Melanomas

Melanomas occur in all domestic animals, but of the large domesticated species, they are most important in the horse. Excessive exposure to sunlight has not been definitively proven to predispose horses to the development of melanoma. A disturbance in melanin metabolism associated with graying has been hypothesized to stimulate formation of new melanoblasts or to stimulate their activity, resulting in focal areas of overproduction in the dermis and epidermis, with subsequent tumor formation.[228] A higher incidence is observed in the Arabian, Lipizzaner, and Percheron breeds, probably because gray coat color occurs more often in these breeds. There is no gender predilection.

Melanocytic skin tumors of horses traditionally have been described in aging gray horses, in *typical* locations: the ventral tail, perineum, external genitalia, lip, udder, and periocular and parotid gland regions. These tumors have been the subject of several classification schemes in attempting to correlate histopathologic appearance with clinical behavior (i.e., benign or malignant). One study distinguished three basic types of melanocytic skin tumors, as discussed next.[229]

Melanocytic nevi (melanocytoma) occur in the superficial dermis or at the epidermal-dermal junction and frequently have epithelial involvement, with nests of relatively large, mildly to moderately pleomorphic cells showing variable cytoplasmic pigmentation and occasional mitoses. More than 70% of these occur in horses less than 6 years of age and may occur in horses of any color (not just gray). Most of these tumors occurred in *atypical* locations. Of 28 melanocytic nevi, only one became invasive; the rest exhibited benign behavior.

Dermal melanomas are found in the deep dermis and are composed of small, homogenous, indistinct tumor cells, either round or dendritic, with no mitoses. (If there are multiple, confluent dermal melanomas, this is referred to as *dermal melanomatosis*). About 80% of these tumors are in horses older than 6 years[229] or

between 5 and 15 years[230] and are much more common in gray horses. Most of these tumors occurred in *typical* locations. Of 14 cases available for follow-up in one study,[229] eight had malignant behavior, as demonstrated by metastases.

In another study, clinicopathologic characteristics of cutaneous melanomas occurring in 83 Camargue-type gray-skinned horses showed that the tumors occurred most frequently underneath the tail (93.9%) and at high rates in the perianal region (43.0%), the lips (33.0%), and the eyelids (24.0%), but rarely in the vulva (3.8%).[231] Microscopic examination indicated that these tumors were composed mostly of melanocytes and numerous melanophages, and that these cells manifested a remarkable cellular atypia. Early stages of the tumors occurred in close association with apocrine sweat glands, but not at the dermal-epidermal junction.

A clinical study was conducted on 296 gray horses of the Lipizzaner breed.[232] Of the 296 horses, dermal melanomas were present in 148 horses (50%), 68 of which were older than 15 years; 51 of these were melanoma bearing. In 75.6% of cases, melanotic tumors were detected underneath the tail. None of the affected individuals had any severe clinical effect or was handicapped in performance. The authors concluded that in contrast to melanomas in solid-colored horses characterized by early metastases, melanomas in gray horses showed less malignancy. Affected individuals often had encapsulated nodules or structures similar to human blue nevi. This finding at least partially reflects confusion in terminology between true malignant melanomas and dermal melanomas.

Anaplastic malignant melanomas are composed of sheets of extremely pleomorphic epithelioid cells with poor pigmentation and many mitoses. These are usually seen in horses older than 20 years of age and occur in horses of any color. Metastasis usually occurs first to the regional lymph nodes, then to the lungs, spleen, and liver. Hematogenous spread may also occur. Metastatic growths may be larger than the primary lesions and softer in consistency.

In regard to treatment, one study reported good success with excising dermal melanomatosis from the perineal, perianal, perirectal, or ventral tail regions.[233] In a study of three horses, cimetidine (2.5 mg/kg PO q8h) was shown to decrease the number and size of melanoma growth.[234] However, a more recent study of 10 horses found that cimetidine had no consistent effects on either the number of tumors or the tumor surface area over the 16 weeks of treatment at 5 mg/kg PO q12h.[235] Another recent article noted a cure rate of 81% for melanomas treated with intratumoral injections of cisplatin.[207]

1330 1331

40.48.2 Bovine Melanomas

Melanomas represented a large proportion of the cutaneous neoplasms of cattle in an older study.[236] The majority are benign, well-differentiated tumors, subcutaneous in location, and without site predilection. Dark-haired cattle are predisposed, particularly the Aberdeen Angus breed. There is no gender predilection.[236] Melanomas usually occur in young cattle and are occasionally recognized as congenital lesions.[237]

40.48.3 Caprine and Ovine Melanomas

Melanomas have been observed only rarely in sheep and goats.[236–239] A survey of 800,000 slaughtered goats revealed only five melanomas.[237] The most common site for melanomas in the goat is the perineal region,[29]

although there is a case report of a malignant melanoma occurring in the coronary band region.[238] Melanomas in Angora goats histologically resemble the corresponding tumors in humans.[239]

40.49 CUTANEOUS LYMPHOSARCOMA

STEPHEN D. WHITE

40.49.1 Equine Lymphoma

Cutaneous lymphoma has occasionally been reported in horses.[240–247] Both T-cell and B-cell forms have been reported. Lesions present as nodules, either cutaneous or subcutaneous. Diagnosis is made by biopsy and, ideally, immunohistochemistry to determine cell type.[246,247] In one horse, progesterone receptors were demonstrated on the lymphoma (B) cells, and the lesions regressed after removal of an estrogen-secreting ovarian tumor.[243] This horse also had a history of partial regression of its tumor after administration of a synthetic progestin, altrenogest (0.044 mg/kg PO once daily for 10 days). Another horse demonstrated reduction in tumor size after administration of another synthetic progestagen, megestrol acetate (0.2 mg/kg PO once daily for 8 days) as well as a local injection of 20 mg betamethasone into a mass.[244] Clearly, treatment is far from standardized, but the progesterone drugs may offer a reasonable treatment modality.

Lymphosarcoma is discussed in Chapter 37.

40.49.2 Bovine Lymphoma

Cattle occasionally are affected by cutaneous lymphoma. The presentation is multifocal intracutaneous nodules, often accompanied by alopecia. Lymphadenopathy, leukocytosis, and lymphocytosis are often present, and internal organs may be affected.[248]

40.49.3 Ovine Lymphoma

There are rare reports of cutaneous lymphoma in sheep.[249,250]

40.50 CYSTS

STEPHEN D. WHITE

Cutaneous cysts are benign lesions characterized by an epithelial wall with keratinous contents. Cutaneous cysts are subdivided into several types on the basis of their histopathologic features.

40.50.1 Epidermal Cysts

Among large animals, epidermal cysts have been reported in horses,[251] cattle,[252] and sheep.[253] These cysts may be more properly called *follicular cysts* because the epithelial lining is probably most often derived from the follicular epithelium rather than the epidermis. The cysts can be found anywhere on the body, single or multiple, congenital or acquired, and generally range in size from 0.2 to 3 cm in diameter. The cysts are covered by intact epithelium and generally do not attach to the overlying epidermis. Microscopically, epidermal cysts

consist of a wall of stratified squamous epithelium surrounding a keratin-filled lumen. Epidermal appendages are not associated with the cyst wall, a feature that distinguishes epidermal from dermoid cysts.

Epidermal cysts are thought to originate from occlusion of a hair follicle or by traumatic implantation of the epidermis. A tentative diagnosis may be made by performing fine-needle aspiration of a lesion and obtaining a fluid that is clear to brownish in color. Aspiration of the contents may temporarily decrease the size of the cyst, but it typically refills. Definitive diagnosis is made by excisional biopsy, which is curative. Epidermal cysts are benign lesions, although painful inflammatory responses and ulceration may result if the cyst is ruptured, with extrusion of contents into the adjacent dermis and subcutis.

40.50.2 Dermoid Cysts

Dermoid cysts are very similar clinically to epidermal cysts but are much less common. Among large animals, they have been identified in horses,[251] goats,[254] and cattle.[255] In cattle, dermoid cysts may be congenital, have been reported to be as large as 10 cm (4 inches) in diameter, and are said to develop most frequently over the cranial area of the thorax[255] and in the pharyngeal region. In horses, dermoid cysts may be single or multiple and are observed most frequently along the dorsal midline between the withers and the croup. Dermoid cysts are believed to result from displacement of embryonic cells into the subcutaneous tissue. They can be distinguished histologically from epidermal cysts by the presence of epidermal appendages within the wall of the cyst and by a lumen that often contains hair and secretions from sebaceous and sweat glands in addition to keratin. As with epidermal cysts, surgical excision is diagnostic and curative.

40.50.3 Dentigerous Cysts

Dentigerous cysts are a congenital defect recognized in horses and are believed to be the result of an abnormality of the first branchial cleft.[256] Clinically, a unilateral saclike swelling that contains embryonic teeth is seen at the base of the ear. The lesion may be firmly attached to the concheal cartilage or temporal bone. Dentigerous cysts tend to fistulate. Treatment consists of surgical excision.[256] Dentigerous cysts have also been reported in sheep and are suspected of being related to a nutritional deficiency of copper.[257]

40.50.4 Wattle Cysts

Wattle cysts are found in goats and usually are present at the base of the wattle. Nubians and Nubian crossbreeds may be predisposed to developing these cysts. The cysts are congenital, but they may not be apparent until the animal is several months old. Tentative diagnosis is based on aspiration of clear fluid, which will temporarily decrease the size of the cyst. Surgical excision is diagnostic and curative. Histologic examination reveals a cyst wall composed of one or two layers of cuboidal to columnar epithelial cells. The cyst cavity contains homogenous, amorphous basophilic substances.[257]

1331 1332

40.51 FROSTBITE

STEPHEN D. WHITE

Frostbite is an uncommon injury among healthy, well-nourished animals, with all species being susceptible. It is caused by prolonged exposure to subfreezing temperatures. The length of time needed to cause frostbite depends

on the ambient temperature, area of the body exposed, and health status. The areas most often affected by cold injury include the ears, tail, teats, scrotum, and distal legs.

Frozen tissue must be handled gently and thawed rapidly in warm water 38° C to 44° C (100.2° F to 111.1° F) as soon as possible after it is known that refreezing can be prevented. Tissue damage is greatly increased if thawing and subsequent refreezing occur (freeze-thaw-freeze-thaw syndrome). Tissue thawing is painful, and analgesics should be administered. Slow thawing is less painful than rapid thawing but results in much greater tissue damage. Frozen tissue should not be massaged during warming. Damaged areas are best left exposed during the healing process rather than covered with occlusive dressings, and premature debridement should be avoided because more tissue may be viable than first apparent. The animal should be given good supportive care and may need to be restrained to prevent self-mutilation. Management practices should be changed to prevent recurrence. Tissues previously damaged by freezing are more susceptible to cold injury when reexposed to subnormal temperatures. [7,258]

40.52 SKIN DISORDERS OF UNKNOWN OR GENETIC ORIGIN

STEPHEN D. WHITE

40.53 EQUINE SEBORRHEA

Several possibly related equine skin diseases characterized by scaling and crust formation are referred to as "seborrhea." Contrary to claims in the older literature, there is little evidence that seborrhea is related to excess sebum production by the sebaceous glands. Most types of seborrhea are probably diseases of abnormal cornification (development of the stratum corneum). Further, most cases reported as "generalized seborrhea" in the horse were probably pemphigus foliaceus, equine sarcoidosis (chronic granulomatous disease), or some other immune-mediated or autoimmune disease. Mane and tail seborrhea is typified by moderate to heavy scaling, with minimal or no pruritus. Some horses have considerable alopecia of the tail.

Cannon keratosis is a common equine skin condition. It involves the cranial surface of the rear cannon bone region and rarely the forelimbs. The lesions consist of areas of scaling and crusting with varying degrees of alopecia. There is no pruritus or other signs of inflammation. Cannon keratosis occurs in both males and mares, so there is no basis for the theory that the condition is caused by urine splatter ("stud crud").[33]

40.54 LINEAR KERATOSIS AND LINEAR ALOPECIA

Linear keratosis and linear alopecia are rare equine dermatoses of unknown cause. There is one report in a cow.[259] The lesions do not follow blood or lymphatic vessels, nerves, or dermatomes. Because both conditions coexist in some horses, it has been suggested that they are variations of the same abnormality, although this is difficult to justify histopathologically. Both conditions have been seen in a wide variety of breeds, but quarter horses appear to be predisposed. Most horses develop lesions between 6 months and 5 years of age.

Linear alopecia is characterized by the gradual development of annular areas of alopecia, usually in a linear, vertically oriented configuration. One or more linear areas may be present. The lesions are usually 2 to 10 mm wide by a few centimeters to over 1 m in length and occur on the neck, shoulder, and lateral thorax. Mild surface scale and crust may be present. The lesions are neither painful nor pruritic. Affected horses are typically otherwise healthy.

Linear keratosis is characterized by the gradual, asymptomatic occurrence of one or more unilateral, linear, vertically oriented bands of hyperkeratotic papules that progress to marked hyperkeratosis and alopecia. The lesions vary from 0.25 to 3.5 cm in width by 5 to 70 cm in length and occur most often over the neck, shoulder, and lateral thorax. Lesions have also been reported to involve the legs, hip, and pectoral region. Again, affected horses are typically otherwise healthy.

These disorders are visually distinctive. Histopathologic findings in linear alopecia include early lymphocytic, infiltrative, mural folliculitis and later granulomatous, infiltrative, mural folliculitis. The mural infiltrate is often directed at the middle area (isthmus) of the follicle. Sebaceous glands may be involved in some cases, and complete follicular destruction and permanent alopecia are seen in severe chronic lesions. Histopathologic findings in linear keratosis include irregular to papillated epidermal hyperplasia and marked compact orthokeratotic hyperkeratosis.[260] I have seen one horse that had lesions grossly diagnosed as linear keratosis, whereas the histopathology had features of both conditions.

Neither condition is known to undergo spontaneous resolution. Owners should be advised of the potential hereditary nature of these disorders. Linear alopecia has been anecdotally reported to respond to topical or systemic glucocorticoids, but recurrence is likely. Response to therapy is more likely to be seen in early lesions, when complete destruction of hair follicles has not occurred. Linear keratosis responds poorly to treatment. Topical keratolytic and keratoplastic agents, such as sulfur/salicylic acid—containing shampoos or 50% propylene glycol, can reduce the hyperkeratosis but must be continued for life. I have had some success using tacrolimus (Protopic, Astellas Pharma US, 0.1% ointment), a drug similar to cyclosporine but better absorbed through the skin, once or twice daily. Because neither condition is symptomatic, observation without treatment may be an acceptable approach.

Interestingly, a report exists of a familial incidence of linear epidermal nevi in Belgian horses.[261]

40.55 ALBINISM

Complete and partial albinism occurs in cattle, sheep, and horses. It is a genetic defect (probably autosomal recessive) in melanin synthesis, resulting in white skin, white hair, pink eyes, and photophobia. In horses, albinism must be distinguished from *lethal white syndrome,* which is primarily a problem in Paint horses (especially, but not exclusively, in overo breedings). The defective gene has also been found in American miniature horses, half-Arabians, thoroughbreds, and cropout quarter horses (foals born to registered quarter horses that have too much white to register as with the AQHA).[262] The Veterinary Genetics Laboratory at UCD offers a diagnostic test to determine carrier status.[*]

The lethality of albinism in horses comes from the association with intestinal aganglionosis. The foals die shortly after birth. Because some white foals are not affected, euthanasia should be performed only after signs of intestinal malfunction occur. This disease is similar to Hirschsprung disease in humans and is linked to a mutation in the endothelin-B receptor gene.[263]

* www.vgl.ucdavis.edu/service/horse/index.html.

40.56 JUVENILE ARABIAN LEUKODERMA (ARABIAN FADING SYNDROME, PINKY SYNDROME, HEREDITARY VITILIGO)

Loss of melanin in the skin (depigmentation) occurs in young Arabian horses 6 months to 2 years of age (Fig. 40-15,*A*). The areas most frequently affected are periocular tissues, muzzle, genitalia, anus, perineum, inguinal region, and undersurface of the base of the tail. Depigmentation may persist, repigment, or wax and wane. The condition is probably hereditary.[33]

40.57 VITILIGO

This condition is best defined as "idiopathic depigmentation." Typically, no trauma has occurred to produce the loss of pigment, and other skin structures are not affected (i.e., no scarring or alopecia) (Fig. 40-15,*B*). There is no known treatment for vitiligo.

40.58 RETICULATED AND HYPERESTHETIC LEUKOTRICHIA

Reticulated leukotrichia occurs mainly in quarter horses, usually as yearlings, and occasionally in other breeds. The lesions occur on the dorsal midline and consist initially of linear crusts arranged in a characteristic cross-hatch pattern (Fig. 40-16). The crusts shed, alopecia occurs, and white hair grows in permanently. There is leukotrichia without leukoderma (depigmented skin). Histologically, these lesions resemble an epidermal form of erythema multiforme, resulting in individual keratinocyte necrosis. *Hyperesthetic leukotrichia* is a similar disease both clinically and histologically, except the crusts are extremely painful to the touch. Within a few weeks, white hairs appear in the affected areas. The crusts resolve, and the pain subsides in 1 to 3 months, but the leukotrichia persists. Several cases have been linked to recent rhinopneumonitis vaccination. These diseases may rarely recur, and there is no known effective treatment.[33]

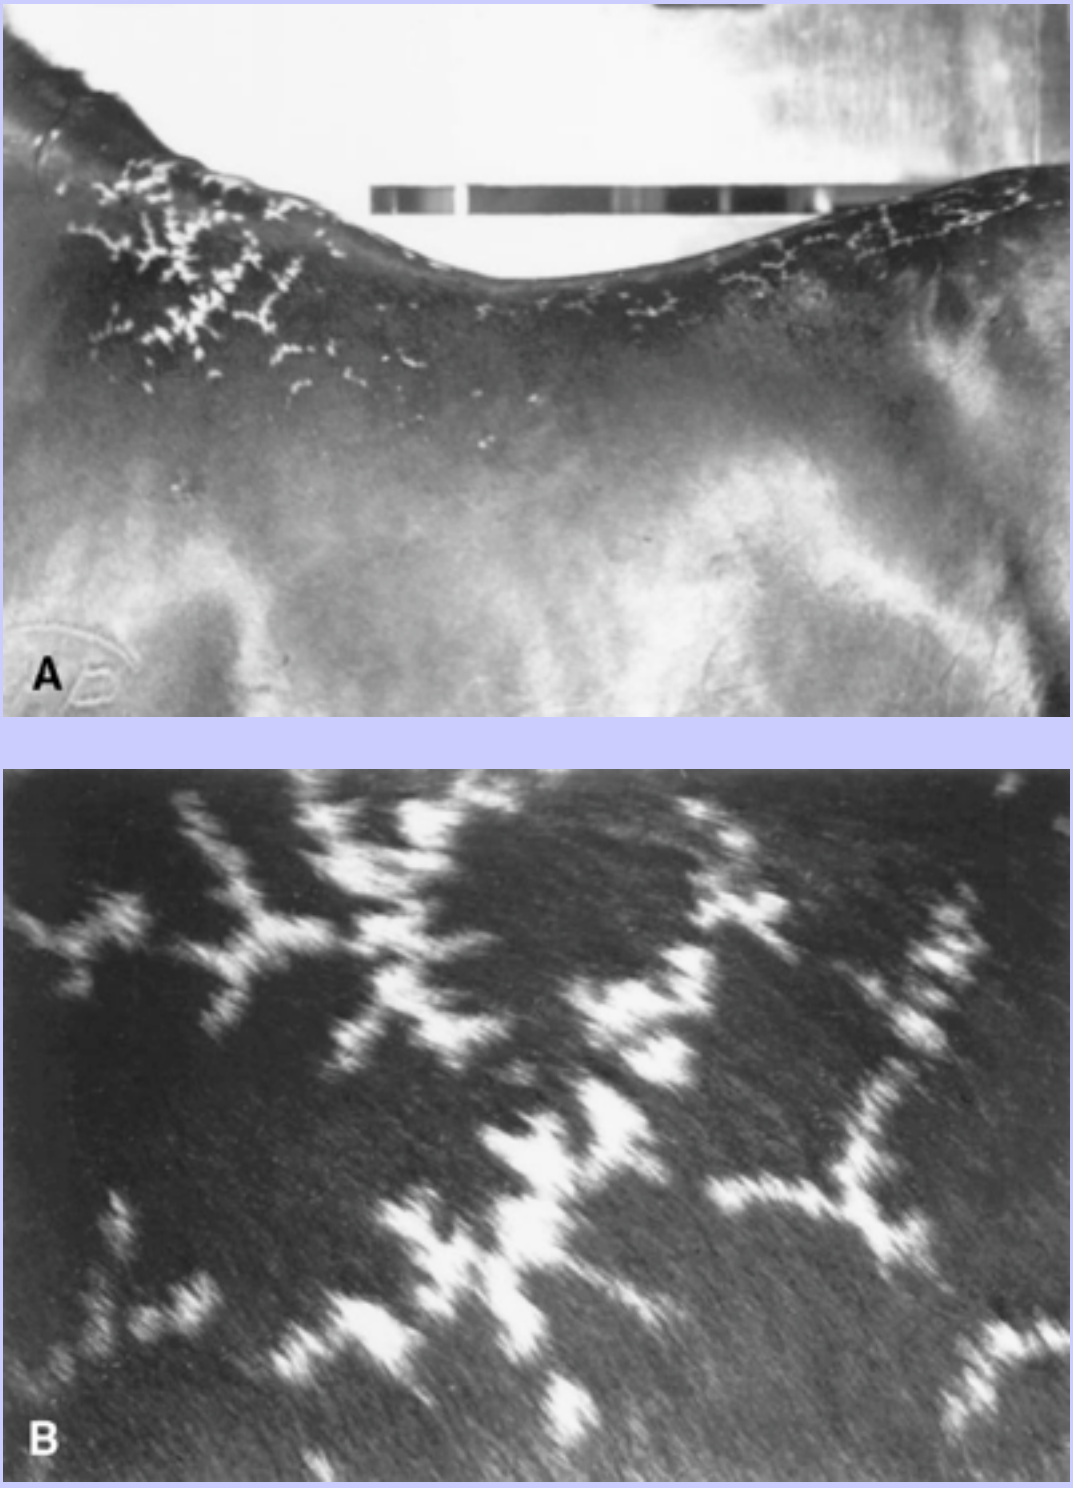
Fig. 40-16 Reticulated leukotrichia in a yearling quarter horse. (Courtesy Dr. Anthony Stannard.)



40.59 HEREDITARY EQUINE REGIONAL DERMAL ASTHENIA (HYPERELASTOSIS CUTIS)

Hereditary equine regional dermal asthenia (HERDA) occurs early in life in horses. Most affected horses are quarter horses, but registered Paint horses and Appaloosas with quarter horse lineage have developed this disease.[264,265] Many of the quarter horses are from high-quality cutting lines. The disease (or similar condition) has also been reported in a crossbred Arabian mare, a thoroughbred gelding, a Hanoverian foal, and a Hafflinger horse.[7,266–268] Rarely, a similar disease has been noted in cattle, termed *dermatosporaxis;* this is caused by mutations in the procollagen I N-proteinase gene.[268,269]

The working hypothesis for HERDA in horses is a defect in the structure or healing process of the collagen fibers in the middle to deep dermis. Typically, these areas are over the back and sides of the neck (Fig. 40-17). The skin in these areas may be easily torn or stretched and often develops seromas and hematomas ("blisters" filled with either serum or blood). Healing is usually adequate but often leaves rather unsightly scars. Diagnosis is often based on the clinical signs alone; histologic findings are sometimes subtle, but "clumped" or poorly organized collagen fibers below the level of the hair follicles may be seen. A zone of middermal to deep dermal separation has been reported in two horses and is present in some biopsy samples.[265,270] "Poorly oriented" collagen fibers are sometimes seen on electron microscopy.

Fig. 40-17 Hereditary equine regional dermal asthenia (HERDA, hyperelastosis cutis) in a horse showing hyperextensible skin. (Courtesy Dr. Anthony Stannard.)

This condition is almost certainly present at birth, but HERDA is often not noticed until about 2 years of age

This condition is almost certainly present at birth, but HERDA is often not noticed until about 2 years of age, when horses start being trained with tack and saddle, and the resulting friction and trauma induce the typical lesions. As with many genetic diseases, no effective treatment or cure exists; some of these horses have been maintained as "pasture pets."

This disease follows an autosomal recessive mode of inheritance, so in order for the foal to be affected, both the sire and the dam must carry the gene, and if they were bred again, there would be approximately a 25% chance that the next foal would also be affected.[271] Recently, a genetic marker was determined for this disease.[271a] The Veterinary Genetics Laboratory at the University of California, Davis offers a diagnostic test to determine carrier or affected status (http://www.vgl.ucdavis.edu/service/horse/index.html). Both carriers and clinically affected horses with HERDA should be removed from breeding programs.

40.60 EPIDERMOLYSIS BULLOSA

Epidermolysis bullosa (EB) includes a number of diseases typified in humans by the common finding of blister formation after minor trauma. Most forms are congenital and apparent soon after birth. In animals and humans, subsets of EB are classified by the histologic location of the blister or cleft. These subtypes (and respective cleft location) are termed EB *simplex* (basal cell layer of epidermis), *junctional* EB (intralamina lucida or basal cell layer), and *dystrophic* EB (sublamina densa).

Junctional EB has been reported in Belgian foals of both genders, in other breeds, and in a donkey.[272–275] Lesions are usually noted within 3 days of birth and include multiple asymmetric skin erosions and ulcers, often encrusted. Lesions may be especially prominent around the coronary bands (causing the hoof to crack and slough) and on the oral, anal, and genital mucosa. Histology and ultrastructural findings indicate a cleft in the intralamina lucida of the basement membrane zone. This is presumably caused by a defect in the anchoring filaments that connect the basement membrane to filaments in the superficial dermis.[273] A laminin-5 defect has been demonstrated in Belgians and in two French draft breeds, Trait Breton and Trait Comtois; the mutation is a cytosine insertion in exon 10 of the LAMC2 gene.[276–278] Because of this knowledge, the Veterinary Genetics Laboratory at UCD offers a diagnostic test to determine carrier status in Belgian draft horses and related breeds.*

Clinical presentation and the age of the foal are highly suggestive of EB diagnosis. Histology and ideally electron microscopy are required to confirm the diagnosis. There is no known treatment, and affected horses, as well as the sires and dams of affected horses, should not be bred; the mode of inheritance is autosomal recessive.

1334

1335

This disease differs from epitheliogenesis imperfecta (see following discussion) in that large areas of the skin are *not* at first devoid of epidermis, but rather lose their skin because of the fibril defect.

* www.vgl.ucdavis.edu/service/horse/index.html.

40.61 EPITHELIOGENESIS IMPERFECTA (APLASIA CUTIS)

Epitheliogenesis imperfecta is a rare inherited congenital discontinuity of squamous epithelium. It is thought to be an autosomal recessive trait and has been reported in several breeds. Lesions are most common on the limbs, head, and tongue. Hooves may slough in severe cases. Clinical presentation is usually diagnostic.[279] In moderately to severely affected animals, the disease is fatal within a few days; the foals die of septicemia or other developmental abnormalities. Mildly affected areas may heal by scar formation. More recent reports suggest that some of these horses (saddlebreds) may have a condition similar to the junctional epidermolysis bullosa in [280–282]

Belgian foals previously noted.[280–282]

40.62 EOSINOPHILIC GRANULOMA (NODULAR NECROBIOSIS, COLLAGENOLYTIC GRANULOMA)

Eosinophilic granuloma is the most common nontumor nodular disease in the author's practice. In most cases the etiology is unknown, although a hypersensitivity reaction to insect bites has been suggested. There is no apparent age, breed, or gender predilection. The disease often begins in warmer months. Lesions up to 5 cm (2 inches) in diameter may be single or multiple and most often affect the neck, withers, and back (Fig 40-18). Skin biopsy reveals multifocal areas of abnormal-staining collagen surrounded by granulomatous inflammation containing eosinophils, lymphocytes, and histiocytes.[33] This is not thought to be caused by "degeneration," but rather by degranulation of eosinophils and the coating of normal collagen fibers with the degranulated material.[283]

Development of equine eosinophilic granuloma has been noted in areas of previous injections using standard silicone-coated, stainless steel hypodermic needles.[284] The reaction may occur at sites of intravenous as well as intramuscular injections. The lesions consist of nonpainful, cool, raised papules or nodules 0.25 to 1 cm in diameter at sites of previous injection. The nodule appears 24 to 48 hours after the injection, and the subsequent eosinophilic granuloma can persist for months to years. Affected horses do not develop a lesion at the site of injection if nondisposable, noncoated needles are used. The use of the noncoated needles is recommended for any horse that develops injection-site collagenolytic granulomas.

Fig. 40-18 Eosinophilic granuloma (nodular necrobiosis), with dermal nodules on the withers of a horse. (Courtesy Dr. Anthony Stannard.)

Horses with solitary or a few lesions may be treated by surgical excision (not in the saddle area) or glucocorticoid

Horses with solitary or a few lesions may be treated by surgical excision (not in the saddle area) or glucocorticoid injections under the lesions. Triamcinolone acetonide (3 to 5 mg per lesion) is effective. It has been recommended that no more than 20 mg triamcinolone acetonide be administered at once to any horse because any more of this drug may cause laminitis.[33] Horses with multiple lesions may be treated with oral prednisolone at 1 mg/kg once daily for 2 to 3 weeks. Multiple, small (<1 cm) lesions may be indicative of insect bite hypersensitivity.

40.63 CUTANEOUS AMYLOIDOSIS

Cutaneous amyloidosis is an uncommon nodular dermatosis of unknown etiology. There is no age, breed, or gender predilection. The condition appears to be a primary form of amyloidosis, in that concurrent inflammatory processes are not present, and amyloid (a fibrillar protein substance derived from immunoglobulins) deposition is usually restricted to the skin and occasionally the regional lymphatics, regional lymph nodes, and upper respiratory mucosa.[7,33] One case was documented as being caused by lambda—light chain deposition from an extramedullary plasmacytoma.[285] Another horse showed amyloidosis concurrent with lymphoma.[286]

Papules, nodules, and plaques on the head, neck, shoulders, thorax, or inguinal areas are firm, 0.5 to 10 cm in diameter, nonpainful, and nonpruritic. The overlying skin is normal, although it may scale or crust in severe cases (Fig. 40-19). The course of cutaneous amyloidosis is progressive and prolonged. Megestrol acetate may be an effective treatment (0.2 mg/kg PO q24h until lesions resolve). Because certain forms of primary amyloidosis in humans have a genetic basis, it may not be advisable to use affected horses for breeding until more is learned about the genetics of the equine disorder.

40.64 EQUINE SARCOIDOSIS (GENERALIZED GRANULOMATOUS DISEASE)

EQUINE SARCOIDOSIS (GENERALIZED GRANULOMATOUS DISEASE)

Equine sarcoidosis is characterized by skin lesions and usually concurrent systemic involvement. It is *not* a neoplastic disease and should *not* be confused with equine sarcoids.

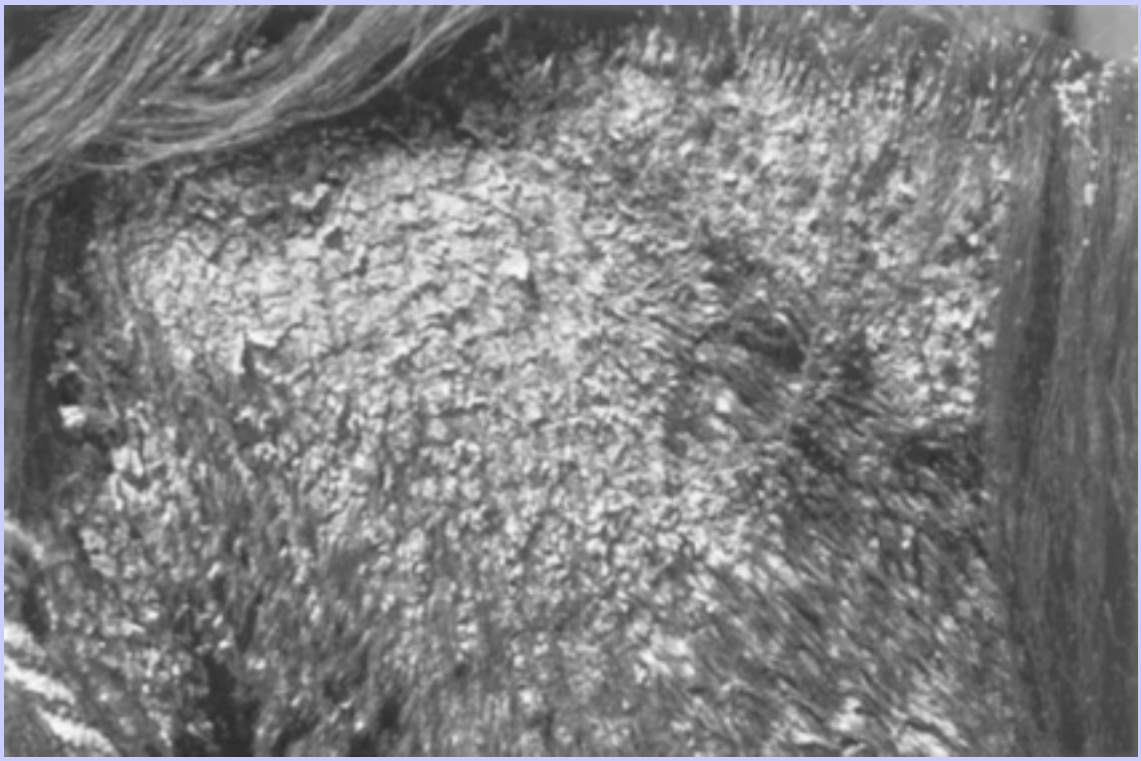
The disease is infrequently encountered, and there is no known breed predilection. Geldings may be at increased risk.[287] The skin lesions typically are generalized scaling and crusting associated with varying degrees of alopecia (Fig. 40-20). Occasionally, the disease is focal or multifocal in distribution. Rarely, the skin lesions consist of nodules or large, tumor-like masses. The different types of skin lesions may coexist. In addition to skin lesions, the most frequent presenting complaints are weight loss, decreased appetite, and a persistent low-grade fever. Lung involvement is manifested by exercise intolerance, increased resting respiratory rate, and mild dyspnea.[288–290] Although one report showed positive titers to *Borrelia burgdorferi* in three of four horses with equine sarcoidosis,[291] a more recent report was unable to demonstrate the presence, using PCR and histologic stains, of any causative organism.[287]

Diagnosis is by histopathology and ruling out infectious etiologies. The major histologic change is the presence of noncaseating granulomas consisting of aggregates of epithelioid cells and multinucleated giant cells. Neutrophils, lymphocytes, and plasma cells are present in small numbers. In the skin the granulomas tend to be located in the superficial portion of the dermis. Because of the small number of horses studied and the variability of clinical signs, response to therapy has not been well documented. A recent abstract reported that five of six horses did well and lived longer than 1 year with prednisolone treatment.[292] Another extensive review showed that some horses did well on corticosteroid therapy (usually at doses approximating those used to treat pemphigus and other autoimmune skin diseases); gastrointestinal involvement was a sign of poorer prognosis.[287]

40.65 PHOTOSENSITIZATION

Photosensitivity is an abnormal reaction of the skin when exposed to light. Photosensitivity in the horse is usually caused by a photodynamic agent in or on the skin that absorbs or transfers energy from light and transfers it to body cells. The activating light is generally in the ultraviolet A (UVA) range (320 to 400 nm). Melanin in the skin screens UV light, thereby limiting photosensitivity reactions to the white and light-colored areas of the body.[293]

Fig. 40-20 Equine sarcoidosis (generalized granulomatous disease) in a horse. In addition to the scaling and crusting skin lesions, the horse has systemic involvement. (Courtesy Dr. Anthony Stannard.)



Photodynamic agents may be drugs, topical medications, foodstuffs, contactants, or excessive phylloerythrin from liver disease. Examples of plants containing photodynamic agents follow:

Common Name	Scientific Name	Agent
St. John's wort	*Hypericum perforatum*	Hypericin
Buckwheat	*Polygonum fagopyrum*	Fagopyrin
Perennial ryegrass	*Lolium perenne*	Perloline
Whiteheads	*Spheosciadium capitellatum*	Unknown

In addition, I have sometimes seen alfalfa or clover induce a photosensitivity reaction; these plants have been suspected to contain either an ingested or contact photodynamic agent. Recent reports describe photosensitivities apparently induced by the ingestion of gluten in horses, and of cocoa shells in calves.[294,294a]

As horses ingest plants containing chlorophyll, this molecule is degraded by bacteria in the intestine into the porphyrin, phylloerythrin. Some phylloerythrin is normally absorbed into the portal circulation, removed by the liver, and excreted by the bile. In liver disease the hepatic excretion of phylloerythrin is decreased, leading to excessive levels in the peripheral circulation and eventually in the skin, causing photosensitivity in approximately 25% of horses with liver dysfunction.[295–297] One of the more common reasons for liver disease in the United

States is ingestion of the following plants containing pyrrolizidine alkaloids:

Common Name	Scientific Name
Common groundsel	*Senecio vulgaris*
Ragwort, stinking Willie	*Senecio jacobea*
Tarweed	*Amsinckia intermedia*
Rattleweed	*Crotalaria* species
Salvation Jane	*Echium lycopsis*

In addition, consumption of alsike clover *(Trifolium hybridum)* may induce hepatic dysfunction (with histologic lesions distinct from those caused by pyrrolizidine alkaloids), leading to photosensitization signs (alsike clover poisoning, dew poisoning). Cases seem to be correlated to years with heavy rainfall and the ingestion of the plant blossoms.[298]

Ingested plants and feed should be noted and collected for future analysis. Environmental considerations include the type of pasture (or other material) with which the animal is in contact, the amount of time the animal is exposed to sunlight, any seasonality of the condition, and any other horses involved. A seasonal incidence would tend to negate liver disease; multihorse involvement should arouse suspicion of an ingested or contact photosensitizer. A thorough history of recent drug therapy should be obtained.

Physical examination usually reveals lesions limited to the hairless, white, or lightly pigmented areas of the skin. The involved skin is erythematous, swollen, and painful. The lesions may progress to serum exudation, thickening, fissuring, and in severe cases, necrosis and sloughing (Fig. 40-21).

Therapy is related to etiology. Chronic liver disease carries a guarded prognosis. Removal of feedstuffs containing photodynamic agents, or removal of the horse from a pasture with plants containing these agents, will usually result in full recovery if the horse is also kept out of the sun for 1 to 2 weeks. Corticosteroids are helpful in controlling inflammation and pruritus. Oral prednisolone at 1 mg/kg daily for 1 week, then halving the daily dosage for a second week, is an effective regimen.

1336

1337

Fig. 40-21 Photosensitization. **A,** White blaze of a horse is selectively affected. **B,** White stocking of a horse is selectively affected. **C,** Area around eye where hair is less dense is most severely affected.

40.66 CHRONIC PROGRESSIVE LYMPHEDEMA

Chronic progressive lymphedema is the term for a condition seen in Shires, Clydesdales, and Belgians. It is characterized by progressive swelling, hyperkeratosis (thickening), and fibrosis (hardening) of the skin on the lower legs. This chronic progressive disease starts at an early age, progresses throughout the life of the horse, and

often ends in disfigurement and disability of the limbs. Inevitably, this condition leads to the horse's premature death. In the Belgian draft horse, it has reduced the average life expectancy of a stallion from 20 to only 6 years.

The pathologic changes and clinical signs closely resemble a condition known in humans as chronic lymphedema, or elephantiasis nostras verrucosa. The lower leg swelling is caused by abnormal functioning of the lymphatic system in the skin, which results in chronic lymphedema (swelling), fibrosis, a compromised immune system, and subsequent secondary infections of the skin. Based on preliminary research, it appears that a similar pathogenic mechanism is involved in the disease that affects these specific draft horse breeds.

The clinical signs of this disease are highly variable. The earliest lesions are characterized by skin thickening and crusting; both are often visible only after clipping the long feathering. Secondary infections develop very easily in these horses' legs and usually consist of either chorioptic mange or bacterial infections. Both dark skin and white skin on the lower legs are equally affected. These lesions are consistent with pastern dermatitis, certainly seen in other breeds. In Shires, Clydesdales, and Belgians, however, these lesions do not respond well to therapy.

1337

1338

As the disease progresses, one or two thick skin folds and sometimes multiple small, well-demarcated ulcerations develop, predominantly in the rear of the pastern region. The ulcerations are covered with adherent crusts. Manual removal of the crusts or even movement during exercise results in bleeding. These small sores may seem to respond initially to various topical medications, but often reverse course, only to progress in severity and multiply in number. Small lesions tend to coalesce into larger and more intractable (resistant to cure) areas of skin ulceration. Over time, the lesions extend up the leg, often affecting the skin as high as the knees or hocks. These lesions are, at the very least, irritating to the horses and at times can be quite painful. Severely affected individuals often exhibit generalized swelling in all four legs.

This condition therefore is primarily a lymph system disease, and the pastern dermatitis in these draft horses is secondary to the body's inability to supply fluids properly and oxygenate the skin of the lower leg. The lymphatics break down over time, and the protein-rich fluid leaks into the tissues of the lower leg, which results in fibrosis of the tissues under the skin and thickening of the skin itself. The tissue fibrosis leads to even more blockage of fluid within the legs, inhibiting circulatory flow. This results in neovascularization, a process by which the body develops new blood vessels in a futile attempt to provide oxygen to its tissues.

Researchers suspect that a deficiency or abnormality in the connective tissue component known as *elastin* is the underlying factor and perhaps the cause of the lymphatic degeneration in these horses.[299,300] In affected animals the lymph vessels and deep tissues of the skin do not have sufficient amounts or the proper configuration of elastin. The lack of this critical tissue element apparently instigates the progression of disease and the chronic progression of clinical signs. A recent report documents high levels of antielastin antibodies in affected horses.[301]

As the condition becomes more chronic, the lower leg enlargement becomes permanent, and the swelling is firm on palpation. More of the thick skin folds and large, poorly defined, firm nodules develop. The nodules may become quite large and often are described as golf ball or even baseball in size. Both skin folds and nodules first develop in the back of the pastern area. With progression, they may extend and encircle the entire lower leg. The nodules become a mechanical problem because they interfere with free movement and frequently are injured during exercise. This disease often progresses to include massive secondary infections that produce copious amounts of foul-smelling exudates, generalized illness, debilitation, and even death.[300,301]

In a recent report of possibly the same condition in several draft breeds, the authors found a perivascular dermatitis dominated by T lymphocytes with an increase in major histocompatibility complex (MHC) class II–positive, dendritic-like cells. Immunohistochemical labeling for cytokeratins CK5/6(4), CK10, and CK14

indicated a change in their expression pattern. This correlated with the degree of epidermal hyperplasia, indicating abnormal differentiation of keratinocytes. There was a statistically significant correlation between the severity of skin lesions and several other factors, including increasing age, increasing cannon circumference, prominence of anatomic structures (e.g., fetlock tufts of hairs, ergots, chestnuts), and bulges in the fetlock region.[302]

41 Chapter 41 Endocrine and Metabolic Diseases

Consulting Editors

Dianne McFarlane

41.1 EQUINE ENDOCRINE AND METABOLIC DISEASES

41.1.1 PITUITARY AND HYPOTHALAMUS

DIANNE McFARLANE

The pituitary gland is composed of two embryologically distinct portions: the adenohypophysis, derived from invagination of the pharyngeal epithelium known as *Rathke's pouch,* and the neurohypophysis, derived from neural tissue of the hypothalamus. The adenohypophysis can be further divided into the pars distalis, pars tuberalis, and pars intermedia. The pars distalis contains five different endocrine cell types, each of which is responsible for the release of a unique hormone or set of hormones in response to hypothalamic releasing factors delivered from the median eminence via the hypothalamic-hypophyseal portal system. The pars tuberalis is a highly vascular band of cells surrounding the pituitary stalk. The function of the pars tuberalis is unclear and has yet to be directly investigated in the horse. The neurohypophysis or pars nervosa is a collection of nerve axons and terminals that originate in the paraventricular and supraoptic nuclei of the hypothalamus. Oxytocin and arginine vasopressin (antidiuretic hormone) produced in the cell bodies of these nuclei are transported into the pars nervosa for storage and eventual release into the systemic circulation.

The pars intermedia of the horse incorporates tissue derived from both the adenohypophysis and the neurohypophysis. It is composed of a single endocrine cell type, the melanotrope. Melanotropes are directly innervated by nerve terminals of the hypothalamic periventricular dopaminergic neurons. These originate in the periventricular nucleus of the hypothalamus adjacent to the third ventricle, project through the infundibulum, and terminate in the pars intermedia (Fig. 41-1).[1] These neurons release the neurotransmitter dopamine, which acts to tonically inhibit the release of hormones from adjacent melanotropes. Dopamine released from the nerve terminals interacts at dopamine (D_2) receptors on the melanotropes to inhibit cell proliferation, transcription of proopiomelanocortin (POMC), and release of POMC-derived peptides.[1] Additional regulatory signals to the pars intermedia may be delivered by direct systemic arterial supply and from the hypothalamic-hypophyseal portal veins.[2] In addition to being under tonic inhibition, melanotropes may also be positively regulated by interaction with a melanotrope-releasing factor. Studies have shown that exogenous thyrotropin-releasing hormone (TRH) can directly stimulate hormone release from melanotropes.[3] However, the physiologic significance of TRH regulation of the pars intermedia has not yet been determined.

The primary product of the melanotrope is the hormone precursor protein POMC. POMC is also expressed by the corticotropes of the pars distalis. However, owing to differential posttranslational processing by proteases called *prohormone convertases,* each cell type secretes a different complement of POMC-derived peptides (Fig. 41-2). Because of the action of prohormone convertase I, POMC in corticotropes is primarily processed into adrenocorticotropin (ACTH). ACTH circulates to the adrenal cortex, where it stimulates secretion of cortisol. Melanotropes contain active prohormone convertase I and II, and therefore POMC in the pars intermedia is cleaved into the secretory peptides α-melanocyte—stimulating hormone (α-MSH), β-endorphin (β-END), and corticotrophin-like intermediate lobe peptide (CLIP). A small amount of ACTH may also be produced. Further

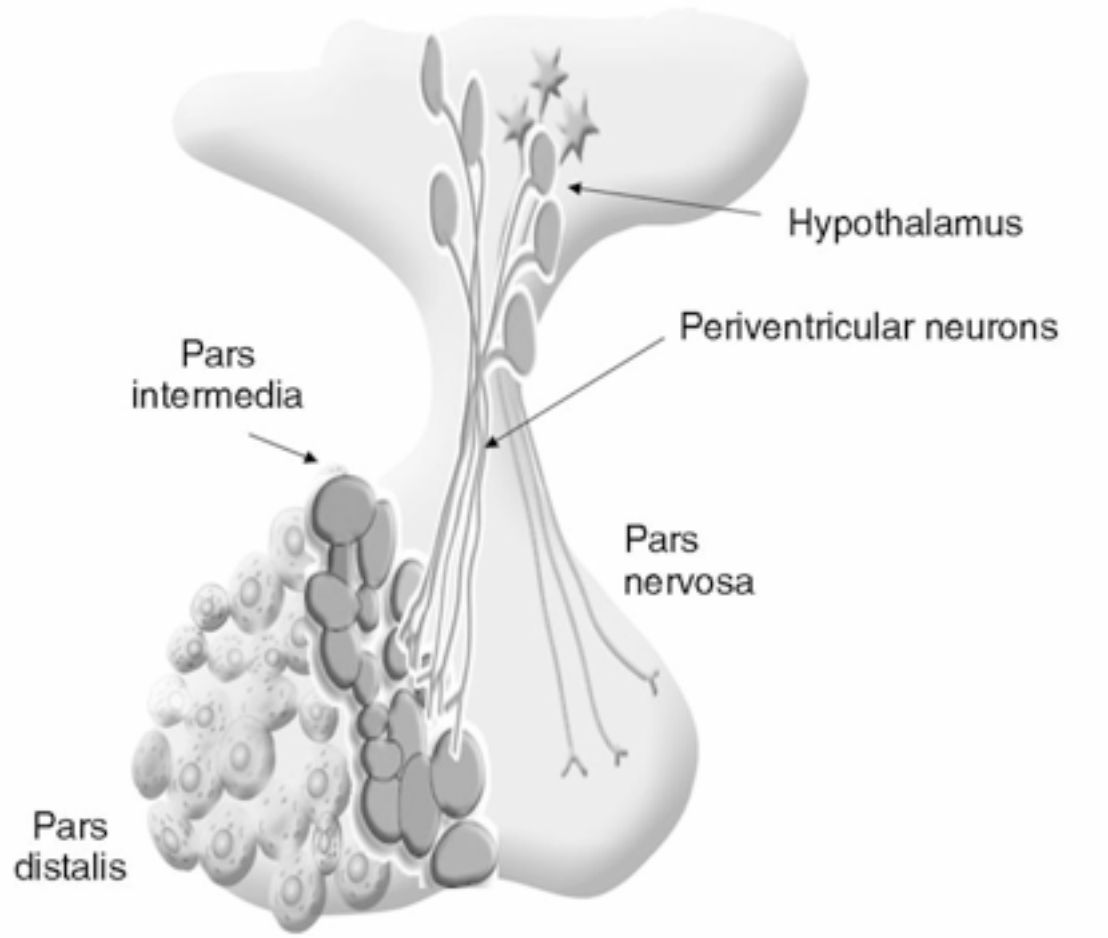
processing of the peptides, including cleavage of C-terminal amino acids and *N*-acetylation, serves to control the activity of the final product. For example, the most abundant form of β-END produced in the normal horse's pars intermedia is Ac-β-endorphin-(1–27), which lacks opioid activity. The most abundant β-END in horses with PPID is β-endorphin-(1–31), which is an opioid agonist.[4]

The physiologic role of the pars intermedia POMC derived-peptides α-MSH, β-END, and CLIP has not been extensively studied in the horse. In other species α-MSH has several diverse actions that are mediated through interaction with one of five distinct G-protein—coupled melanocortin receptors. α-MSH is so named because of its ability to induce skin pigmentation in amphibians. Its role in pigmentation is through interaction with melanocortin receptor 1 (MC1R), which is predominantly expressed in skin. In horses, mutation of the *MC1R* gene is associated with the chestnut coat color.[5] In white Camarque horses the degree of coat pigmentation is directly correlated to the plasma concentration of α-MSH.[6] α-MSH is also an integral mediator in control of energy homeostasis. MC3R and MC4R are both expressed in the central nervous system (CNS), particularly in the hypothalamus, where they function in the leptin-melanocortin pathway, regulating appetite-satiety balance and fat metabolism.[7] Animals and humans lacking functional MC3R or MC4R are obese, and melanocortin receptor defects are a common monogenetic cause of obesity in humans.[8] Plasma α-MSH concentration in obese men has been reported to be higher than in lean men.[9] It has been suggested high plasma concentration in obese individuals may be an attempt to maintain homeostasis in individuals with a defect in MC4R. Plasma α-MSH concentration was also found to be positively correlated to obesity in horses.[10] Another function of α-MSH is as a potent antiinflammatory agent.[11] α-MSH has been demonstrated to have multiple immune-modulating effects. Its most profound effect is in regulation of cytokine response. α-MSH inhibits activation of nuclear factor (NF)-κB by lipopolysaccharide (LPS) and interferon-γ (IFN-γ). Recent data in mice have suggested that α-MSH may suppress LPS-mediated inflammation by facilitating the interaction of interleukin receptor-associated kinase (IRAK) and IRAK-M. IRAK is a kinase that functions in activation of NF-κB after TLR-4 (the receptor for bacterial LPS) stimulation.[12] IRAK-M is a negative regulator of IRAK. As a result, NF-κB activation and proinflammatory cytokine release of tumor necrosis factor alpha (TNF-α), interleukin (IL)-1β, and IL-6 are all decreased after α-MSH administration. Fever and other clinical evidence of inflammation are also reduced.

1339

1340

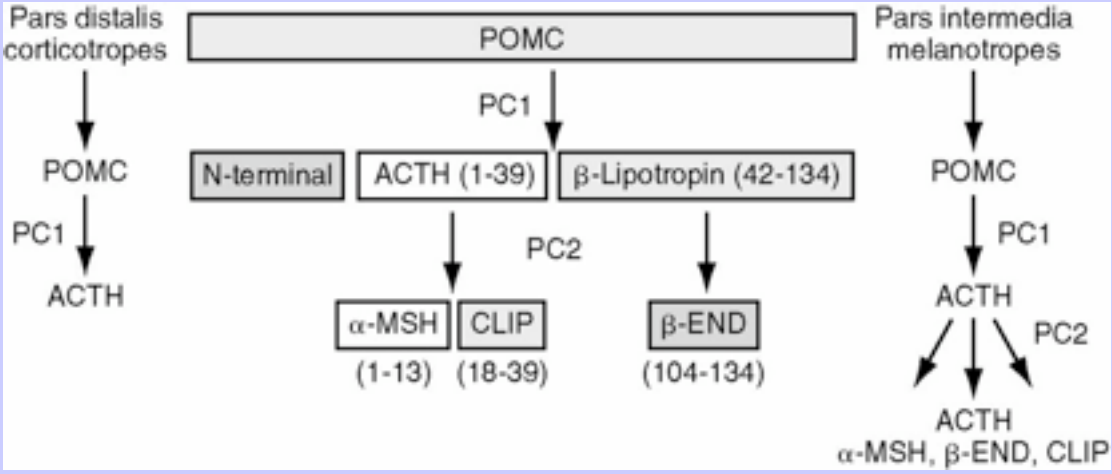
Fig. 41-1 Physiology of the equine pituitary pars intermedia. The melanotropes of the pars intermedia produce the hormone precursor protein, proopiomelanocortin (POMC), which in the pars intermedia is cleaved into the hormones α-melanocyte—stimulating hormone (α-MSH), β-endorphin (β-END), and corticotrophin-like intermediate lobe peptide (CLIP). Production of POMC in the pars intermedia is under inhibitory control by dopamine released from the nerve terminals of the periventricular neurons. The cell bodies of the periventricular neurons are in the hypothalamus, adjacent to the third ventricle.



β-END is a known endogenous opioid. Secretion of β-END provides analgesia and behavioral modification. It also suppresses immune responsiveness and has effects on vascular tone.[13–14] CLIP (ACTH 18–39) has not been extensively studied in any species. In pancreatic islet cells in culture, CLIP was shown to be a pancreatic

beta cell secretagogue, stimulating the release of insulin.[15] However, when administered to rats by either intraperitoneal or intraventricular injection, ACTH but not CLIP resulted in release of insulin and decrease in blood glucose.[16]

Fig. 41-2 Proopiomelanocortin (POMC) processing. POMC is cleaved by prohormone convertase I into ACTH in the pars distalis and into α-melanocyte stimulating hormone, β-endorphin, and corticotrophin-like intermediate lobe peptide by prohormone convertase I and II in the pars intermedia. Only a small amount of ACTH is produced by the normal pars intermedia.



Recent data have demonstrated a distinct seasonal effect on the activity of the pars intermedia of horses and ponies residing in the northeastern United States and Canada.[17] Plasma α-MSH concentration was considerably higher in horses and ponies in September compared with samples collected in the winter, spring, and early summer. An effect of season on α-MSH concentration has been described for humans, hamsters, and sheep.[18–20] The functional importance of the seasonal cycle is unknown, but several physiologic events occur in parallel with the α-MSH cycle. In sheep, body weight, voluntary food intake, and condition all peak simultaneously with α-MSH, with seasonal maximums occurring in September. Soay sheep with surgically created hypothalamic-pituitary disconnection have an increase in circulating concentration of α-MSH and chronic increase in body weight.[19] These findings suggest that α-MSH or other POMC-derived peptides may play a role in metabolic preparation for winter in sheep. It is possible that horses and ponies have a seasonal increase in POMC-derived peptides to metabolically prepare them for a decrease in accessible food observed in the wild in winter. If so, dysregulation of this pathway might be associated with abnormalities in body weight and fat storage. Weight loss and abnormal fat distribution are two clinical signs associated with equine pituitary pars intermedia dysfunction (PPID). Development of a winter coat also begins as length of day decreases in the fall. The development of hirsutism in horses with PPID leads one to speculate that the naturally occurring seasonal increase in POMC-derived peptides contributes to development of winter coat growth. This has not been critically assessed in equids.

41.1.1.1

Equine Pituitary Pars Intermedia Dysfunction

PPID is one of the most common diseases of horses and ponies 15 years of age and older.[21] PPID was originally termed “equine Cushing's disease” because of features similar to human Cushing's disease. However, in contrast to human Cushing's disease, PPID affects the pituitary pars intermedia rather than the pars distalis and is typically not a neoplastic condition, and the adrenocortical contribution to the clinical syndrome is of much less importance.[22] To avoid confusion, equine Cushing's disease is now more correctly referred to as *pituitary pars intermedia dysfunction*.

In the past two decades the population of aged horses has increased dramatically. This, in conjunction with the vast amount of information available to the horse-owning public, has lead to a heightened client awareness of age-associated equine health issues and a desire to promote healthy aging in their horses. As a result, diagnostic testing and treatment of horses for PPID has increased. Yet despite increased clinical recognition of this disease, much about PPID remains poorly understood.

1340

41.1.1.1.1

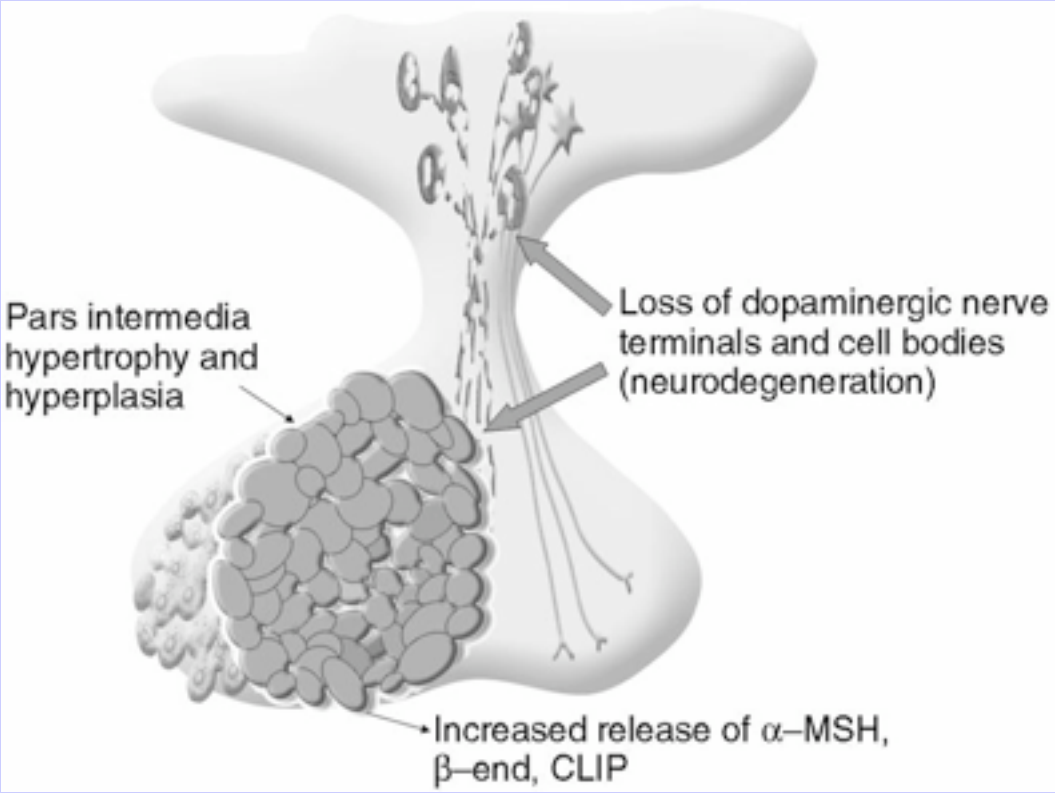
1341

Pathophysiology

The pathologic hallmarks of PPID are hypertrophy, hyperplasia, and microadenoma or macroadenoma formation in the pituitary pars intermedia that results in an increased secretion of POMC peptides. Horses with PPID develop enlarged pituitaries that may reach five times normal weight. As the pars intermedia expands, it compresses the adjacent pituitary lobes and hypothalamus, often resulting in a loss of function of these tissues. In contrast, the pars intermedia remains active in horses with PPID, secreting relatively large quantities of POMC-derived peptides into the peripheral circulation. Horses with disease may have as much as a 40-fold increase in plasma concentration of pars intermedia POMC-derived peptides.[23] Clinical signs of disease likely result from a combination of increased circulating POMC peptides and loss of neuroendocrine function of adjacent tissues.

Evidence indicates loss of dopaminergic inhibition is critical in the pathology of PPID. Dopamine and dopamine metabolite concentrations in the pars intermedia of PPID horses are decreased eightfold compared with age-matched controls.[6] Systemic supplementation of dopamine or a dopamine agonist to horses with PPID results in a decrease in plasma concentration of POMC peptides.[23] Several investigators have reported that horses treated with the dopamine agonist pergolide show improvement in both clinical signs and biochemical abnormalities associated with disease.[24–26] Immunohistochemistry of formalin-fixed tissue showed a fivefold decrease in pituitary dopaminergic nerve terminals ($P < .001$) and a 50% reduction in the number of dopaminergic periventricular cell bodies ($P < .01$) in the hypothalamus of PPID animals.[27] This evidence suggests that a loss of functional periventricular dopaminergic neurons or “dopaminergic neurodegeneration” occurs in horses with PPID (Fig. 41-3). Loss of periventricular dopaminergic inhibition of the pars intermedia in other species results in pathologic changes similar to those of PPID. Surgical disruption of the periventricular hypophyseal dopaminergic tracts in rats results in increased expression of pars intermedia melanotropes.[28] In addition, D_2 dopamine receptor knockout mice develop pars intermedia lesions similar to PPID.[29] These data suggest PPID is primarily a disease of hypothalamic origin rather than the consequence of a spontaneously forming pituitary adenoma.

Fig. 41-3 Pathophysiology of equine pituitary pars intermedia dysfunction. Loss of functional dopaminergic periventricular neurons leads to a decrease in dopamine at the pars intermedia. This in turns results in disinhibition of the melanotropes of the pars intermedia. The outcome is hypertrophy and hyperplasia of the pars intermedia and increased systemic release of the pars intermedia POMC-derived peptides, α-melanocyte—stimulating hormone (α-MSH), β-endorphin (β-END) and corticotrophin-like intermediate lobe peptide (CLIP).



One potential cause for dopaminergic neurodegeneration is oxidative stress. Oxidative stress is modification of cellular components including proteins, DNA, and cell membrane lipids because of excessive exposure to exogenous or endogenous sources of free radicals. This cellular damage ultimately leads to cell death or, in the case of neurons, neurodegeneration. Chronic exposure to oxidants in excess of an animal's antioxidant capacity results in accumulation of functionally impaired cellular components. Dopaminergic neurons are particularly vulnerable to oxidative damage, because dopamine metabolism itself produces free radicals. Horses with PPID have evidence of oxidative damage, including

accumulation of pars intermedia 3-nitrotyrosine[27] and decreased plasma thiol.[30] This oxidative damage does not appear to be the result of impaired antioxidant capacity, as the systemic and pituitary antioxidant capacity of horses appears unchanged.[31]

41.1.1.1.2

Clinical Signs

Equine PPID affects many aged equids, resulting in a variety of clinical signs including hirsutism, laminitis, muscle atrophy, fat accumulation, polydipsia, polyuria, secondary infections, lethargy, infertility, persistent lactation, hyperhidrosis, and metabolic abnormalities including hyperglycemia (Fig. 41-4).[32] The most unique clinical manifestation of PPID is an abnormally long, curly hair coat that fails to shed, referred to as *equine hirsutism*. Often horse owners may report the horse shedding its winter coat slowly or incompletely in the year(s) prior to development of full hirsutism. Hair may be initially retained along the legs or under the mandible. The mechanism responsible for development of hirsutism in horses with PPID has not been investigated. The onset of hirsutism in an aged horse or pony is considered essentially pathognomonic for PPID.

Laminitis secondary to PPID is reported to occur in 24% to 82% of diagnosed cases and frequently necessitates euthanasia in affected animals.[32–35] When adult horses with laminitis of unknown origin were examined, 70% had increased ACTH, suggesting that laminitis in these animals may have been the result of undiagnosed PPID.[36] This study suggests PPID may be underdiagnosed, especially when laminitis is the presenting complaint and hirsutism is absent. The pathogenesis of laminitis in PPID is not currently understood but is the subject of ongoing investigation. It has been suggested that laminitis secondary to PPID is the consequence of high circulating cortisol concentration. However, the inability to induce experimental laminitis in normal horses using corticosteroids indicates the pathogenesis is more complex. Recent data have shown that glucose deprivation in the laminar tissue of the hoof, as would occur with insulin resistance (IR) secondary to endocrinopathy or exogenous glucocorticoid administration, may result in failure of the energy-dependent reactions required to maintain the laminar attachments known as *hemidesmosomes*.[37] Inflammatory cytokine and matrix metalloproteinase activation has been suggested to have a role in acute laminitis associated with endotoxemia or grain overload and may similarly contribute to laminitis in horses with endocrine dysfunction.[38,39]

1341

1342

Fig. 41-4 Typical horse with pituitary pars intermedia dysfunction (PPID). This 22-year-old Morgan mare shows obvious hirsutism. Other clinical signs of PPID included laminitis and weight loss despite an excellent appetite.

In the author's experience, weight loss caused by muscle mass atrophy is the most common and possibly earliest clinical sign of PPID (Fig. 41-5). Despite weight loss, PPID horses often have a potbellied appearance, and as a consequence owners may fail to notice the lost weight. Weight loss and muscle atrophy may result from several factors including poor dentition, poor nutrition, heavy parasite burden, minimal exercise, and protein catabolism induced by increased cortisol activity. Histologic evidence of type 2 myofiber atrophy has recently been documented in muscle biopsies from horses with PPID, consistent with corticosteroid-associated muscle atrophy in other species.[40] Response to treatment with the dopamine agonist pergolide was assessed in three horses. Pergolide treatment was associated with an improvement in myofiber type composition, although myofiber ratio and cross-sectional area were no different. Improvements in management of PPID horses often result in significant weight gain, even in the absence of pharmacologic treatment.

Despite weight loss and muscle mass atrophy, horses with PPID often have abnormal accumulations of fat, most notably in the crest of the neck, tailbase, sheath, and superorbital fossa. This fat accumulation typically predates the weight loss and has a similar pattern as that observed in horses with equine

metabolic syndrome (EMS). The similarity of these two diseases, in both the breeds that are predisposed and clinical signs, has resulted in misdiagnosis of PPID in animals with EMS. There has also been speculation that animals with EMS or sustained obesity with IR may be at greater risk for developing PPID as they age. Although epidemiologic data are currently lacking to support this association, client-provided anecdotal data suggest this may warrant more critical assessment.

Fig. 41-5 Horse with pituitary pars intermedia dysfunction (PPID). The major clinical sign of disease in this horse with PPID was weight loss. Muscle mass atrophy along the dorsum, with a potbelly appearance, is characteristic of PPID.

Polyuria and polydipsia (PU/PD) have been estimated to occur in 17% to 76% of cases and are typically mild in severity.[32–34,41,42] The mechanism responsible for PU/PD may include (1) compression of the pars nervosa resulting in decreased arginine vasopressin (AVP; antidiuretic hormone) production; (2) osmotic diuresis secondary to hyperglycemia and glucosuria; or (3) factors that are cortisol induced. Cortisol is thought to cause PU/PD in other species by interfering with the secretion and/or action of arginine vasopression.[43] Evidence suggests that ACTH and cortisol may inhibit the renin-angiotensin-aldosterone axis, as well. The mechanism of PU/PD in horses with PPID has not been extensively examined. Glucosuria is not a common finding in horses with PPID. In one study, two PPID horses with marked hyperglycemia were found to have water consumption similar to that of normal horses.[35] These findings suggest it is unlikely that osmotic diuresis is a major mechanism of PU/PD in the PPID horse.

Horses with PPID have been reported to be more susceptible to infection, including endoparasitism, bacterial sinusitis, skin infections, foot abscesses, and respiratory infections.[32] The morbidity and mortality of secondary infection in equine PPID has been reported to range from 27% to 48%.[33–34,41,42] In the absence of parasite control, a heavy parasite burden is common. Routine, quantitative fecal egg counts are recommended to ensure an adequate anthelmintic program. Vigilance on the part of the owner and veterinarian is important in both prevention and early recognition of infections, as they may be clinically insidious. Bronchopneumonia was found at necropsy in 7 of 19 horses with PPID.[36] Bronchopneumonia should be considered in the PPID horse with fever or tachypnea and ruled out in horses with intermittent hyperhidrosis.

41.1.1.1.3

Diagnosis

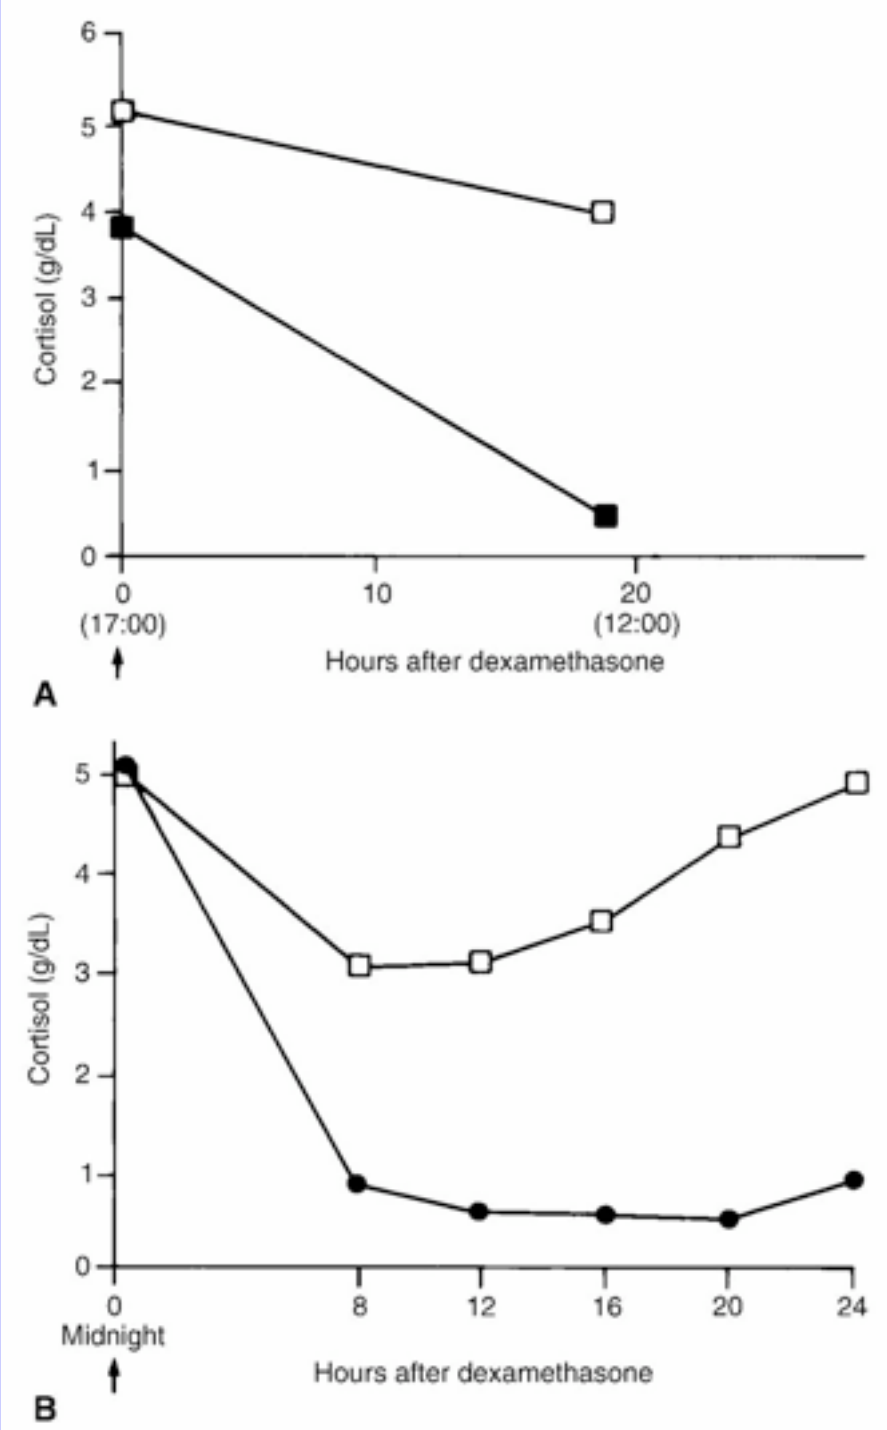
Equine PPID is both common and life-threatening; therefore early and accurate diagnosis and intervention are imperative. Antemortem diagnosis of PPID currently relies on testing hypothalamic-pituitary-adrenal axis responsiveness or measurement of endogenous plasma concentrations of POMC-derived peptides, such as ACTH. These tests have been the subject of recent evaluation, and the search for new testing strategies is ongoing.

The overnight dexamethasone suppression test (DST) has been considered the gold standard for antemortem PPID diagnosis. In the unaffected horse, intramuscular administration of dexamethasone decreases release of ACTH from the pars distalis, resulting in a serum cortisol concentration of less than 1 μg/dL (27.59 nmol/L) 19 hours after dexamethasone administration (Fig. 41-6).[22] Horses with PPID fail to suppress serum cortisol concentration as a result of ACTH production from the pars intermedia. Originally this test was reported to have a sensitivity and a specificity of 100%.[22] However, a recent report suggests the reliability of the test has been overestimated.[44] When the DST was performed three times at 30-day intervals in seven horses with clinical signs of PPID, only one of the seven horses tested positive for disease on all 3 days. After an initial positive result, five of the seven horses suppressed normally on each subsequent test date, indicating either false-positive results at the initial test period or false-negative results at subsequent testing. These findings are consistent with the observations of the author. Horses with a normal dexamethasone suppression response have been found to have an increased plasma concentration of ACTH or α-MSH and postmortem histologic evidence of pars intermedia adenomatous hyperplasia. Although it has not been critically assessed, a loss of feedback inhibition by glucocorticoid may be a late event in the disease progression, and the high sensitivity originally reported may reflect a case selection bias toward horses with advanced disease. Despite these limitations, the overnight DST remains the test of choice for diagnosis of PPID in the animal when the risk of laminitis is minimal and more intensive testing (DST and TRH) is not practical. In horses in which clinical examination suggests early PPID and diagnostic test results are normal, repeat testing is recommended 6 months later or sooner if clinical signs progress.

1342

1343

Fig. 41-6 Dexamethasone suppression test. □, Cushing's; ▪, control; ↑, 40 mcg of dexamethasone intramuscularly. **A,** Overnight. **B,** Standard.



Seasonal variation in DST results has been recently documented.[45] Clinically healthy horses and semiferal ponies residing in Pennsylvania had a normal DST in January, but when the same animals were tested in September, 40% of the horses and 21% of the ponies failed to suppress. Other diagnostic tests have also been shown to be affected by season. Plasma ACTH concentration measured in September was significantly higher than in January or May.[45] In plasma samples collected in September, 85% of horses and 97% of semiferal ponies had ACTH concentrations greater than reference range. These animals would have been falsely diagnosed with PPID. In contrast, 100% of the horses and 98% of the ponies had ACTH concentrations within reference range when measured in January or May. Similarly, plasma α-MSH was increased twofold in horses residing in Prince Edward Island, Canada and elevenfold in semiferal ponies in Pennsylvania when measured in the fall compared with spring, summer, or winter concentrations.[17] The effect of season on diagnostic testing needs to be more extensively explored using a larger number of animals in diverse geographic locations.

The TRH stimulation test is also used for diagnosis of PPID, particularly in horses with a history of laminitis. Horses with PPID show an increase in serum cortisol concentration 30 to 90 minutes after TRH administration, whereas normal horses do not.[46] TRH is believed to be a physiologic releasing factor of the equine pars intermedia.[3] In healthy horses, α-MSH (a pars intermedia product) increased over 600% after TRH administration. The exaggerated cortisol release after TRH administration in horses with PPID may be the result of failure of the enzyme prohormone convertase 2 to keep up with the POMC production in the hypertrophic pars intermedia melanotropes, resulting in preferential accumulation and secretion of ACTH. Evaluation of the predictive value of the TRH stimulation test has not been critically assessed in a large number of horses. In one study, 5 of 15 horses without clinical or histologic evidence of PPID had a greater than 50% increase in cortisol 30 minutes after TRH administration.[3] These horses would have been falsely identified as having PPID. Historically, TRH stimulation test was limited by the lack of availability of TRH approved for use in the horse and the high price of human-approved products. The current availability of compounded TRH and its apparent lack of adverse effects have resulted in this test being employed more frequently in field practice.

A diagnostic test that may have better performance than either the DST or the TRH stimulation test is the combined dexamethasone suppression and TRH stimulation test. Sensitivity of the combined dexamethasone suppression and TRH stimulation test has recently been critically evaluated in 42 horses, using histology for diagnosis.[47] Disease was defined as the presence of a discrete mass in the pars intermedia. Horses were included into the study based on availability (horses donated during the time span of the project). This differs from previous studies in which inclusion was based on presence or absence of clinical signs of disease. The method of selection used in the current study is more random and therefore more appropriate for determining sensitivity and specificity of a diagnostic test. Based on histology, prevalence of PPID was 40% in horses of all ages (2 to 33 years) and significantly correlated with age. Sensitivity of the combined test was reported as 88% and specificity as 76%. This test has the disadvantage of requiring multiple sampling over 2 days and an increased cost compared with other methods.

Endogenous concentrations of POMC-derived peptides are also useful in diagnosis of PPID. Increased plasma concentrations of ACTH, α-MSH, and β-END have all been shown to have a sensitivity and specificity of approximately 80% to 90%.[34,48] However, because the DST was used as a gold standard, it is likely these studies overestimate the validity of measurement of POMC-derived peptide concentration in the diagnosis of PPID. Measurement of ACTH is perhaps the most commonly used method for diagnosis

of PPID in ambulatory practice because it requires collection of only a single plasma sample and poses no risk to the patient.

Imaging of the pituitary using computed tomography (CT) has also been examined in a limited number of cases as a method for documenting pituitary enlargement.[49,50] Accuracy of CT at estimating width, height, and length of the equine pituitary gland in disarticulated heads from 25 normal horses was determined to be 81% to 93%, 58% to 71%, and 88% to 99% respectively.[51] Accuracy for volume was calculated to range from 43% to 53% in the same study.[51] Although magnetic resonance imaging is the preferred diagnostic imaging modality for pituitary masses in humans, there are no reports of its use in diagnosis of PPID in the horse.

1343

1344

41.1.1.1.4

Necropsy Findings

Postmortem examination of the horse with PPID reveals a grossly enlarged pituitary resulting from hypertrophy and hyperplasia of the pars intermedia. The normal horse's pituitary typically weighs 1 to 3 g; the affected horse's pituitary may be two to five times this weight. Enlargement may be the result of an adenoma (>1 cm), which often contains areas of hemorrhage and necrosis. Alternatively, microadenomatous (≤1 cm) hyperplasia may be present. Melanotropic tumor cells are pleomorphic (polyhedral or spindle shaped) with eosinophilic, granular cytoplasm.[52,53] Cells are organized into nodules, rosettes, bundles, or follicular structures separated by fine septal tissue. Pigment deposition is common in the pars nervosa, and hemosiderin may be observed when hemorrhage is present. Other lesions include compression of the pars distalis, pars nervosa, or, in the case of large tumors that outgrow the sella turcica, compression of the optic chiasm or hypothalamus. Other gross lesions may include those related to disease complications such as laminitis, intestinal parasitism, pneumonia, or sinusitis.

41.1.1.1.5

Treatment and Prognosis

Treatment of PPID is aimed at improving general health and reducing the risk of disease complications such as laminitis and immunosuppression. Management practices should be optimized for care of an aged horse. Diet and feeding practices, dental and hoof care, and deworming schedule should be assessed. Feeding of a pelleted diet designed for senior horses and frequent deworming and correction of dental abnormalities are useful in maintaining the animal's weight and improving overall general health. Body clipping the horse with hirsutism during the warm weather is critical to limit hyperhidrosis and avoid hyperthermia. Vigilant observation for evidence of infection or laminitis followed by early intervention is important in avoiding protracted illness.

Pharmaceutical therapies for PPID function by decreasing the concentration of circulating POMC peptides and/or cortisol, which theoretically should reduce the risk of disease complications beyond what can be achieved by management alone. Ideally, treatment should also reverse or retard the hyperplastic growth of the pars intermedia, thereby limiting compression of adjacent tissues. However, minimal data are available evaluating the long-term efficacy of medical therapy for PPID.

The current preferred drug for the treatment of PPID is pergolide, a dopamine agonist. Several reports have indicated that pergolide improves clinical signs and diagnostic test results in treated animals.[24–26] An initial dose of 0.002 mg/kg orally every 24 hours has been recommended.[32] If no response is observed in 4–12 weeks, the dose is increased in 0.002-mg/kg increments monthly until clinical signs and biochemical

abnormalities normalize. A total dose of 0.01 mg/kg should not be exceeded.[32] Complications associated with pergolide use in the horse include anorexia, colic, and diarrhea. These are typically dose dependent and resolve spontaneously after a reduction in dose. Once an effective dose is established, endocrine testing should be repeated every 6 to 12 months to ensure hormonal control is maintained.

Cyproheptadine, a drug with antiserotoninergic, antihistaminergic, and anticholinergic activity, was one of the original drugs used to treat horses with PPID. However, several studies using measurable outcomes failed to show consistent efficacy of the drug.[24,26] In addition, although historically inexpensive, cyproheptadine has increased significantly in cost, making pergolide the more rational treatment choice. Cyproheptadine may be useful as an adjunct therapy in horses resistant to pergolide monotherapy. Cyproheptadine may be added at 0.3 to 0.5 mg/kg orally once daily to horses that show minimal response to 0.004 to 0.006 mg/kg of pergolide.[32]

A newer treatment available in Europe is trilostane, a competitive inhibitor of 3β-hydroxysteroid dehydrogenase (HSD). Trilostane blocks cortisol production by the adrenal gland. In a report of 20 clinical cases diagnosed using the combined DST suppression and TRH stimulation test, trilostane at a dose of 0.4 to 1 mg/kg once daily resulted in improvement of clinical signs and normalization of cortisol after TRH administration 30 days after starting therapy, although baseline cortisol remained unchanged.[54] Adverse effects of trilostane were not reported in this study. The effectiveness of trilostane as a monotherapy or in combination with pergolide remains to be evaluated in a large number of horses. One potential limitation of trilostane as a monotherapy in the treatment of PPID is the lack of downregulation of the pars intermedia melanotropes. Therefore a continued elevation in plasma POMC peptide concentration and enlargement of the pars intermedia would be an expected outcome.

The prognosis of horses with PPID is not well documented. Many horses live for years after diagnosis, particularly if receiving optimized management. Anecdotal reports of PPID horses that have responded to pergolide for more than 4 years suggest treatment may remain effective long term. As with all diseases, early recognition, appropriate intervention, and avoidance of complications are the keys to a positive outcome.

41.1.1.2

DIABETES INSIPIDUS

NOEL O. DYBDAL

DIANNE McFARLANE

Neurogenic diabetes insipidus results from decreased release of AVP from the posterior pituitary. As already noted, the most common cause of decreased AVP release in the horse is posterior pituitary destruction secondary to pars intermedia enlargement; however, in rare cases, idiopathic neurogenic diabetes insipidus has been reported in the horse.[55] The clinical presentation of PU/PD in an otherwise normal animal must include as differential diagnoses primary renal disease, nephrogenic diabetes insipidus (insensitivity of the kidneys to AVP), psychogenic PD syndrome, PPID, and diabetes insipidus caused by posterior pituitary dysfunction unrelated to PPID. In the horse with idiopathic diabetes insipidus, urine specific gravity is less than 1.01. The affected animals fail to concentrate urine on a water deprivation test. In one reported case the horse responded to exogenous AVP (40 U of pitressin tannate in oil intramuscularly [IM]) with a decrease in water consumption and concentration of the urine, which lasted approximately 24 hours.[55] Blood AVP concentrations were low compared with controls and did not change in response to water deprivation.

Although relatively uncommon, psychogenic PD syndrome occurs in horses. When subjected to a deprivation test, horses with psychogenic PD will moderately concentrate urine (up to 1.025). AVP levels in this disorder have not been reported. With renal disease, specific gravity rarely falls below 1.010, and other laboratory findings (e.g., elevated blood urea nitrogen, creatinine) are consistent with the diagnosis. The same is true of PPID. Because the PU and PD of PPID are not entirely related to decreased AVP levels, affected animals frequently respond normally to water deprivation.

1344

1345

41.1.2

ADRENAL GLANDS

NOEL O. DYBDAL

DIANNE McFARLANE

The paired adrenal glands in the horse lay craniomedial to the kidneys. The adrenal glands weigh 15 to 17 g each and are 9 to 10 cm in length, 3 to 4 cm wide, and 1.5 cm thick. The right adrenal is medially adherent to the vena cava and cranially lies in the impression in the liver formed by the right kidney. The left adrenal is associated with the cranial mesenteric artery on its medial border, the aorta and renal artery on its dorsal border, and the left aspect of the pancreas on its ventral border.[56] The glands are well vascularized. The adrenal cortex is composed of the outermost zona glomerulosa, which produces mineralocorticoids, primarily in response to angiotensin II and falling serum sodium levels; the zona fasciculata, which produces glucocorticoids in response to stimulation by ACTH; and the zona reticularis, responsible for adrenal androgen production. The centrally located adrenal medulla produces catecholamines. In the horse the primary adrenal medullary catecholamine appears to be epinephrine; however, norepinephrine and dopamine are also produced and secreted to some extent.[57] The adrenal glands are a shock organ in the horse, and adrenal hemorrhage and necrosis are common sequelae to conditions such as severe bouts of endotoxemia and colic.

41.1.2.1

ADRENAL EXHAUSTION

Adrenal exhaustion or “let down” syndrome are much discussed, poorly documented syndromes ascribed to adrenal insufficiency in the horse. Low cortisol levels have not been found in racehorses that turn in poor performances blamed on adrenal exhaustion.[58] Abnormal response to ACTH challenge has not been noted in endurance horses after 22.4-km (36-mile) rides.[59] Low circulating cortisol levels have been noted after 160-km (100-mile) rides; however, adrenal function was not assessed by any provocative tests in this study.[60] At necropsy it is more common to find enlarged adrenal glands in racehorses than it is to find atrophic glands. This hypertrophy may be the result of repeated administration of exogenous ACTH, which in turn could lead to “let down” when injections are discontinued, or it may be caused by chronic stress. Because the adrenals are a shock organ in the horse, they can be damaged (e.g., by hemorrhage and necrosis, which can lead to subsequent scarring) during bouts of endotoxemia, severe colic, or anaphylaxis. Chronic administration of corticosteroids can also lead to adrenocortical insufficiency.

Adrenal insufficiency should be considered in the differential diagnoses of horses with depression, anorexia, weight loss, hyponatremia, hypochloremia, hyperkalemia, or hypoglycemia, particularly if the horse has recently come off the track or some other form of intensive training or corticosteroids have been administered. An ACTH stimulation test can be used to confirm the diagnosis; cortisol should increase twofold to threefold 2 to 4 hours after stimulation.

41.1.2.2

PHEOCHROMOCYTOMA

Although adrenal medullary tumors are generally nonfunctional tumors noted incidentally at necropsy, there are a few case reports in the literature of functional adrenal medullary tumors in horses.[61,62] Clinical signs are attributable to increased circulating catecholamine and include excessive sweating (hyperhidrosis), apprehension, recurrent colic, tachycardia, dilated pupils, hyperglycemia, and hypertension. Pheochromocytomas are predisposed to hemorrhage, and severe hemorrhage secondary to ruptured pheochromocytoma has been reported in horses.[62] Although most cases are diagnosed at necropsy, determination of urinary catecholamine levels can aid in antemortem diagnosis.

41.1.2.3

ANHIDROSIS

Babetta A. Breuhaus

41.1.2.3.1

Description of Disease

Anhidrosis is characterized as an inability to sweat in response to appropriate stimuli. It occurs in geographic areas that experience hot, humid weather for prolonged periods of time. Clinical signs are especially likely to occur when nighttime temperatures do not fall below 70° F. Classically, anhidrosis affects horses that are not accustomed to these environmental conditions and are moved to a hot, humid area. However, partial or complete anhidrosis is also diagnosed in horses that have grown up in the same areas. It appears that horses that are worked or exercised in hot, humid conditions are more likely to develop the condition than horses that are not worked. Stress may also contribute to onset of the problem. Epidemiologic studies performed in the mid 1980s concluded that there was no sex or breed predisposition to the condition.[63,64] However, it is the author's subjective impression that thoroughbreds (and Appendix registered quarter horses) and warmbloods are more likely to be affected.

41.1.2.3.2

Etiology and Pathophysiology

The cause of anhidrosis is unknown. Presumably there is an abnormality in stimulation or production of sweat. Equine sweat glands produce sweat as an ultrafiltrate from plasma; water and electrolytes are secreted into sweat gland ducts, and this fluid is transported to the skin surface as sweat. Physiologic stimulation of sweating in horses is achieved by activation of β_2-adrenergic receptors, both by direct neural stimulation and from circulating catecholamines.[65–67] Sweat glands from anhidrotic horses do not respond normally to direct stimulation, and there is histologic evidence of sweat gland atrophy.[68,69] However, it is unknown whether the observed sweat gland atrophy is the primary cause of anhidrosis or merely secondary to disuse. Histologic examination of skin from anhidrotic horses also showed no evidence of neural disruption to the sweat glands,[69] and circulating concentrations of epinephrine are actually higher in anhidrotic horses than in horses that sweat normally,[70] suggesting that the problem is more likely caused by decreased ability of sweat glands to respond to stimulation, rather than failure of the thermoregulatory system to perceive the need to sweat or failure of stimulation to sweat. Most theories of pathogenesis of anhidrosis suggest downregulation or desensitization of the β_2-adrenoreceptors, but to date no studies have demonstrated either one of these or an alternative mechanism.

In addition to a neural mechanism, there may also be an endocrine component to this disease. Pregnant mares were found to be somewhat less at risk of developing anhidrosis than nonpregnant mares.[64] An association of anhidrosis with hypothyroidism most likely stems from the observation that thyroid supplementation helped anhidrotic horses racing in Hong Kong in the 1950s.[71] However, the author has not observed any improvement in anhidrotic pleasure horses supplemented with thyroid hormones, and measurement of thyroid hormones at rest and in response to TRH showed no difference between normal horses and horses with anhidrosis.[72]

There is evidence in some humans that acquired idiopathic anhidrosis may have an immunologic pathogenesis. Serum IgE concentration was increased in one reported case.[73] Sweat gland atrophy with infiltration by lymphocytes and mast cells and IgG and C3 deposition in the basement membrane has been described.[73,74] Steroid therapy improved the ability of one of these patients to sweat. An immune-mediated basis for anhidrosis has not been studied in the horse. Basement membrane was noted to be thickened in skin biopsies from 10 anhidrotic horses.[69] However, inflammation (i.e., infiltration with white blood cells) was noted in only one of six anhidrotic horses housed at ambient conditions.[69]

1345 1346

Results of a recent study showed that expression of the water channel aquaporin-5 was decreased in sweat glands from anhidrotic horses compared with sweat glands from horses that sweated normally.[75] Although these results may help explain why hypohidrotic or anhidrotic horses cannot produce as much sweat as normal horses, it is not clear whether loss of these water channels is a cause or a consequence of decreased sweat gland secretory capacity.

41.1.2.3.3

Clinical Signs and Differential Diagnoses

Early clinical signs of hypohidrosis include exercise intolerance, particularly in warm humid weather, and tachypnea, initially during or after exercise and then at rest as the severity of disease increases. Owners may call the veterinarian thinking the horse has a respiratory problem. As hypohidrosis worsens or the horse becomes anhidrotic, owners realize the horse is not sweating as much as they would expect for the level of work it is performing, or it is taking longer than normal to cool out after exercise. Areas of residual sweat production often include under the mane, in the axilla or inguinal areas, and under the saddle. Body temperature can increase to dangerous levels if signs are not recognized, and affected horses continue to work in hot weather. The hair coat often becomes dry and thin in chronically affected horses, particularly over the face (Fig. 41-7) and cannon bones.

41.1.2.3.4

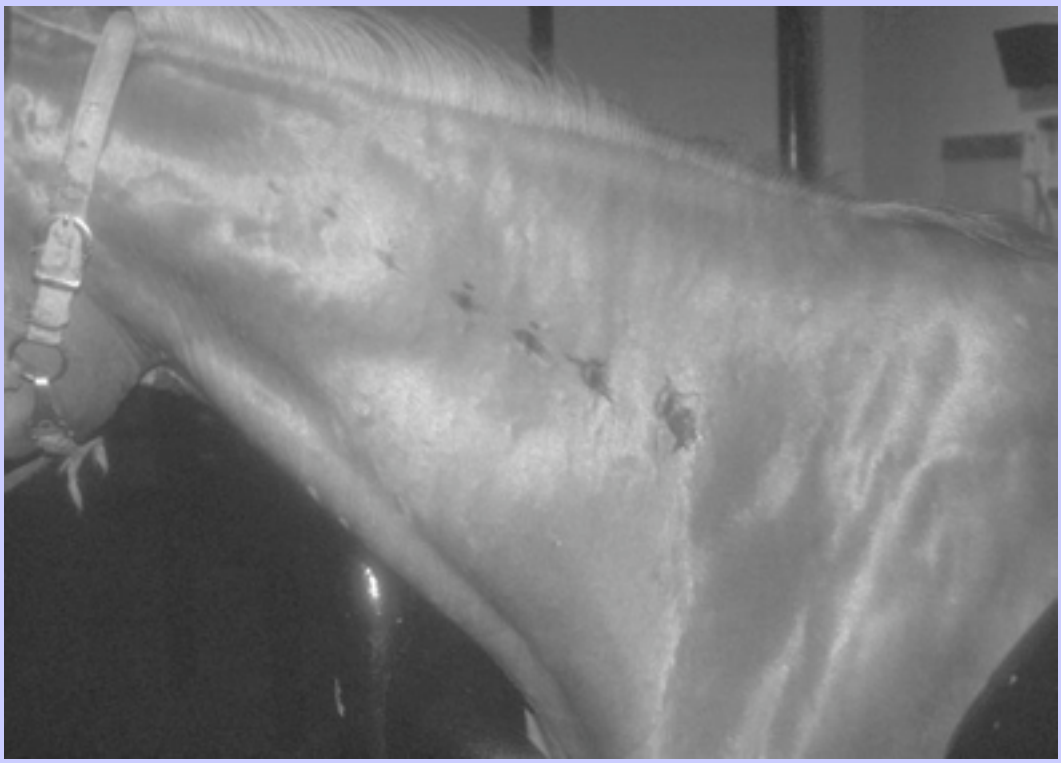
Clinical Pathology and Diagnostic Tests

Hypohidrosis or anhidrosis can be included in a differential diagnosis of exercise intolerance based on history and clinical signs. The diagnosis can be confirmed by performing an intradermal sweat test.[68,76–78] Six serial tenfold dilutions of a β_2-adrenergic agonist such as terbutaline (10^{-3} w/v to 10^{-8} w/v) are prepared. Each dilution (0.1 mL) is injected intradermally along the neck or in the pectoral region. In normal horses a localized area of sweat will appear at the site of injection at all concentrations, except perhaps the most dilute concentration (i.e., 10^{-8}). The amount of sweat produced at each site is proportional to the concentration of terbutaline injected (Fig. 41-8). Sweating will first be noted in normal horses within 5 minutes of injection at the higher concentrations. Onset of sweat production may be

delayed and amount of sweat reduced in hypohidrotic horses, or hypohidrotic horses may sweat only at the higher concentrations of terbutaline. Anhidrotic horses do not sweat, even at the highest concentration.

Fig. 41-7 Chronic anhidrosis often causes facial hair loss or thinning.

Fig. 41-8 Terbutaline intradermal sweat test. Six serial tenfold dilutions of terbutaline are injected intradermally along the neck. Normal horses, such as the one shown here, will sweat at the injection site of all concentrations, except perhaps the most dilute (10^{-8} w/v). In the normal horse, sweating will typically begin within 5 minutes of injection. Reduction in the amount or delay in onset of sweating is diagnostic for hypohidrosis. A complete failure to sweat in response to all terbutaline injections is diagnostic for anhidrosis.



Although failure to sweat in response to intradermal terbutaline injection confirms a diagnosis of anhidrosis, horses that are hypohidrotic may continue to produce sweat, even at the lower concentrations. For these horses, a lunge test will help confirm the diagnosis. Body temperature, heart rate, and respiratory rate are recorded. The horse is then lunged at a trot for 30 minutes on a hot day. During this time, the horse is observed for evidence of sweat production. Body temperature, heart rate, and respiratory rate measurements are made immediately at the end of lunging and every 10 minutes thereafter for the next 30 minutes. Although the heart rate response reflects the degree of fitness, the body temperature and respiratory rate responses correlate better to the horse's ability to cool itself. If the horse's respiratory rate is not back to what is was before the onset of lunging by 30 minutes after the end of the exercise, it is

highly likely that the horse is having a problem cooling. Rarely, horses unable to secrete fluid sweat are observed to secrete salt crystals after a lunge test (Fig. 41-9).

The most likely differential diagnoses for hypohidrosis include various respiratory diseases. In my experience, some hypohidrotic or anhidrotic horses also have mild airway inflammation, documented most often by increased mast cells or eosinophils in bronchoalveolar lavage fluid. It is unknown whether the two problems coexist coincidentally or if there is a mechanistic link. Either way, it is likely that airway inflammation would decrease the ability of a horse to use its respiratory system to help cool itself, and this is likely to be more critical in a horse that cannot sweat.

41.1.2.3.5

Treatment, Prevention, and Prognosis

1346

The only consistently successful treatment is movement of the horse to a cooler environment, although this is not always practical or feasible. Other environmental or dietary alterations may or may not be helpful. 1347 For hypohidrotic horses or horses that are having their first episode of anhidrosis, it is important to stop any workload and decrease the stress level. Concurrent disease conditions such as airway inflammation should be appropriately treated. Shade, fans, misting fans, and window air conditioners can be used to try to decrease the temperature in the horse's local environment. Applying water by hose or sponging the horse with water during the hot part of the day can take the place of sweat. Electrolyte supplementation (especially KCl) has been advocated,[78] and various products are available commercially that appear to help some but not all horses. One such supplement contains L-tyrosine, ascorbic acid, niacin, and cobalt and claims to improve sweat production by supplying precursors to dopamine synthesis (One AC, MPCO, Phoenix, Ariz.). The theory is that dopamine improves skin vasodilation, resulting in increased blood flow to sweat glands during exercise. To the author's knowledge no studies at present support or refute this claim. Other treatments that have been used with mixed success include acupuncture and Chinese herbs.[78]

Fig. 41-9 Salt crystals secreted in response to exercise (lunge test) in an anhidrotic horse. After a lunge test, this horse excreted salt crystals *(shown here)* without a fluid component to the sweat. The author has observed this in two horses diagnosed with anhidrosis.

Medical therapy of anhidrosis has primarily been unrewarding. Anecdotally, the β_2-adrenergic agonist clenbuterol increases sweat production in hypohidrotic horses and may be beneficial if used sparingly, only when weather conditions are particularly bad (i.e., extremely high heat and humidity). However, traditional recommendations are to avoid use of β_2-adrenergic agonists in hypohidrotic horses because their use may precipitate complete anhidrosis.[79] There is increasing evidence in human medicine that combination treatment of chronic airway disease with both β_2-adrenergic agonists and corticosteroids results in a synergistic effect, with corticosteroids helping to prevent desensitization and tolerance to β_2-adrenergic agonists, and β_2-adrenergic agonists potentiating the antiinflammatory effects of the corticosteroids.[80,81] Thus, combination therapy may be useful in hypohidrotic horses, but to date no controlled studies have been performed. Corticosteroid therapy may also be useful if there is an immune component to the pathogenesis of anhidrosis.

Once a horse has had an episode of anhidrosis, there are certain measures that can be taken to try to prevent recurrence of the problem in subsequent years. Before the hot part of the year begins, start the horse on any supplements that have been helpful previously and make certain the horse is cardiovascularly fit. Also, make sure that any respiratory problems are under control before the onset of hot weather. As the hot season approaches, try to avoid procedures (e.g., dental procedures) that might require administration of heavy doses of α_2 sedatives that stimulate the horse to sweat. Plan to do these procedures during the cooler parts of the year. During hot periods, work the horse only during the cool parts of the day. Use external water sources to decrease the need for the horse to sweat.

The prognosis for hypohidrotic horses is guarded for future athletic performance in a hot environment. It is the author's opinion that the longer an anhidrotic horse has been left untreated or unmanaged, the less likely the horse will be to sweat again despite any of the treatments described earlier. However, if an underlying disease or problem can be identified and treated successfully in a horse that is just becoming hypohidrotic, the likelihood that the horse will sweat better the following season is improved.

41.1.3 THYROID GLANDS

BABETTA A. BREUHAUS

Thyroid gland physiology and control of thyroid hormone secretion in horses is similar to that in other species. Thyroid hormones are important for growth, maturation of organ systems, and regulation of metabolism. They stimulate protein synthesis and catabolism, increase body heat production, and stimulate basal metabolic rate. The thyroid gland concentrates iodides from the blood and synthesizes and secretes both thyroxine (T_4) and triiodothyronine (T_3). Once secreted, thyroid hormones circulate both bound to proteins and unbound (“free”), with the free fractions being the active fractions. T_3 is more metabolically active than T_4, and although some T_3 is secreted by the thyroid gland along with T_4, the main source of T_3 in the body is from conversion of T_4 to T_3 in peripheral tissues.

Thyroid hormone secretion is regulated by the hypothalamus and pituitary. TRH from the median eminence of the hypothalamus stimulates release of thyroid-stimulating hormone (TSH) from the anterior pituitary; TSH travels in the blood to the thyroid gland to stimulate release of thyroid hormones. Circulating thyroid hormones exert negative feedback on the hypothalamus and pituitary to limit further release of TRH and TSH. Neurotransmitters that play a role in thyroid hormone regulation include α-adrenergic agonists (stimulatory)

and somatostatin and dopamine (inhibitory). Glucocorticoids and the cytokines TNF and IL-1β also inhibit TSH secretion.

Alterations in thyroid hormone status that have been described in horses include thyroid gland neoplasia, hyperthyroidism, and hypothyroidism. Certain drugs, diets, and physiologic or pathophysiologic states can also influence circulating thyroid hormone concentrations. Although equine thyroid dysfunction has been reviewed fairly recently,[82,83] a number of studies of equine thyroid function and dysfunction have been performed since that time or are in progress.

1347 1348

41.1.3.1

THYROID GLAND NEOPLASIA

Thyroid gland neoplasias are not uncommon, and it is not unusual to find them as incidental findings during necropsy of older horses.[84,85] Thyroid adenomas are most common, but other reported thyroid neoplasias include carcinomas, adenocarcinomas, and C-cell tumors. Although there are also scattered case reports in the literature of horses that were found to be hypothyroid or hyperthyroid because of a thyroid tumor, most thyroid gland tumors are benign and nonfunctional. The glands enlarge physically, but there is no metastasis, and circulating thyroid hormone concentrations remain within normal limits. Therefore treatment of most thyroid gland neoplasias is unnecessary until or unless the glands become big enough to start to interfere with swallowing or breathing. Once a thyroid gland tumor becomes enlarged enough for the owner to notice it, a reasonable approach would be to measure circulating thyroid hormones (both total and free concentrations of T_4 and T_3). Provided that the horse is comfortable, the tumor is not big enough to interfere with alimentary or respiratory function, and the circulating thyroid hormone concentrations are normal, surgical removal is not mandatory. The size of the gland should be monitored. If the gland starts to enlarge rapidly or if circulating thyroid hormone concentrations increase, it is best to surgically remove the gland sooner, not later. Once the thyroid glands have been removed, the horse should be treated with thyroid hormone supplementation as needed to maintain circulating concentrations of thyroid hormones within the normal reference range.

41.1.3.2

HYPERTHYROIDISM IN ADULT HORSES

Hyperthyroidism is extremely rare in horses. There are two documented case reports in the literature, and both of these were associated with thyroid gland neoplasia.[86,87] Circulating thyroid hormone concentrations are also sometimes temporarily increased in horses exposed to excess iodine, such as in a topical blister. Clinical signs of hyperthyroidism in horses include weight loss, tachycardia, tachypnea, hyperactive behavior, ravenous appetite, and cachexia. Diagnosis is confirmed by measurement of increased circulating concentrations of free fractions of thyroid hormones. Treatment of a hyperactive thyroid tumor is thyroidectomy. If only one half of the thyroid gland is removed, thyroid hormone supplementation may not be necessary.

41.1.3.3

HYPOTHYROIDISM IN ADULT HORSES

Hypothyroidism in the horse is poorly understood, and its existence is controversial. Although autoimmune thyroid disease is somewhat common in people and dogs, it has not been described in the horse. The prevalence of true hypothyroidism in adult horses is unknown but is almost certainly overestimated. Hypothyroidism has been thought to contribute to a variety of problems in the horse, including obesity, laminitis, anhidrosis, recurrent rhabdomyolysis, and poor fertility. However, proper documentation of hypothyroidism in such cases for the most part does not exist. Anecdotal reports of beneficial effects of

thyroid hormone supplementation in these horses are also largely unsubstantiated. Despite this, many horses with these conditions receive unnecessary thyroid hormone medication over extended periods of time. Besides the obvious waste of money, potential health risks associated with inappropriate thyroid hormone supplementation are only beginning to be explored in horses. In humans, thyrotoxicosis or oversupplementation with levothyroxine can result in decreased bone density, increased risk of atrial fibrillation, and perhaps increased risk of myocardial infarction or congestive heart failure.[88]

Clinical signs of hypothyroidism in adult horses appear to be subtle. Traditionally, horses that gained weight easily, had cresty necks, and tended to have recurrent bouts of laminitis were thought to be hypothyroid. However, in the author's experience results of thyroid function tests in horses that fit this description are usually normal, and it is more likely that these horses have either EMS or PPID. In a few published case reports of horses that were documented to be hypothyroid, clinical signs were primarily lethargy, exercise intolerance, and poor hair coat.[89,91] In experiments in which horses were made hypothyroid either by surgical removal of the thyroid glands or by administration of antithyroid drugs,[92–96] obesity and laminitis were not reported. Although resting heart rate, cardiac output, respiratory rate, and rectal temperature decreased in horses after thyroidectomy,[93] and serum concentrations of triglycerides, cholesterol, and very—low-density lipoproteins (VLDLs) increased,[94] the changes were mild, and absolute values remained within the normal reference range for adult horses. For this reason, measurement of these values would not help identify a hypothyroid horse in the general population.

41.1.3.3.1

Other Alterations of Thyroid Function

Certain drugs, diets, physiologic, or pathologic states can alter thyroid hormone synthesis, metabolism, or binding, resulting in altered serum concentrations of thyroid hormones. For example, fasting lowers circulating concentrations of thyroid hormones in many species studied, including the horse.[97] Phenylbutazone or dexamethasone administration, strenuous exercise, and diets high in energy, protein, zinc, and copper have also been shown to alter circulating concentrations of thyroid hormones in horses.[98–105]

41.1.3.3.2

Nonthyroidal Illness Syndrome

Nonthyroidal illness syndrome has been described in humans, dogs, and cats with systemic illnesses but has not been studied extensively in horses. A preliminary report by the author suggests nonthyroidal illness syndrome is similar in horses compared with other species.[106] In humans, milder forms of illness result in decreases in serum concentrations of T_3, with T_4 remaining within the normal range or slightly decreased. As nonthyroidal illness becomes more severe, total T_4 decreases, and eventually free T_4 also begins to decrease. The magnitude of thyroid hormone suppression has been correlated to severity of disease and mortality.[107–109] Mechanisms by which thyroid hormones decrease during illness include decreased peripheral conversion of T_4 to T_3 by 5'-deiodinase, altered binding to serum carrier proteins, and hypothalamic-pituitary dysregulation or suppression.[109–113]

41.1.3.3.3

Fescue Ingestion

Tall fescue *(Festuca arundinaceae)* is a perennial grass that is grown commonly in the Southeast because it is relatively easy to establish, has a long growing season, and has good disease and drought resistance,

which allows it to survive hot, humid summers. Various reproductive problems have been described in mares consuming fescue that have been shown to be caused by alkaloids produced by an endophytic fungus *(Neotyphodium coenophialum)* that lives symbiotically on the fescue plant. These alkaloids act as a dopamine agonist (for a recent review, see Evans).[114] Because TSH release from the pituitary is inhibited by dopamine,[115] it has been suggested that fescue consumption could lead to secondary hypothyroidism. Fescue ingestion was proposed as the cause of lower serum TSH concentrations in mares and foals consuming endophyte-infected fescue on a central Kentucky farm, compared with neighboring mares and foals grazing mainly endophyte-free fescue pastures.[116] However, when adult, nonpregnant horses were fed endophyte-infected fescue seed for 2 months there was no differences in baseline concentrations of thyroid hormones, TSH, or responses to administration of TRH.[117] It appears that dopamine acts more as an acute modulator of TSH secretion, rather than as the primary control. In humans, although acute dopamine blockade results in increased TSH secretion and increased circulating thyroid hormones, chronic administration does not cause long-term alterations in thyroid hormone status.[115] Therefore it is likely that compensatory mechanisms override any dopaminergic effect of chronic fescue ingestion in the horse.

1348

1349

41.1.3.3.4 Syndromes Historically Associated with Hypothyroidism

41.1.3.3.4.1 OBESITY

As mentioned earlier, horses that gain weight easily and have a tendency to deposit fat in the crest of the neck, over the rump and tailhead, or in the sheath have long been regarded as hypothyroid. It is now known that these horses are likely to have normal thyroid function and to be insulin resistant. Anecdotally, thyroid hormone administration to these horses usually does not result in weight loss. This is especially true if feed consumption is not restricted and if the amount of thyroid hormone supplementation is titrated to maintain serum thyroid hormone concentrations in the normal reference range. However, because thyroid hormone supplementation decreases blood lipid concentrations and improves insulin sensitivity and disposal in normal horses,[118] it is possible that thyroid hormone supplementation may be useful to help obese horses with metabolic syndrome lose weight. If thyroid hormones are given for this purpose, it is important to understand that they are being used as a pharmacologic tool for a short period of time, and lifelong administration is not indicated. When thyroid hormones are used to help obese horses lose weight, it is likely that the amount of hormone given needs to be enough to make the horse mildly hyperthyroid. Feed intake must also be controlled at 1.5% to 2% of desired body weight per day of grass hay or other feed that is low in soluble carbohydrates.

41.1.3.3.4.2 LAMINITIS

A role for decreased thyroid function in the pathogenesis of laminitis is poorly documented and remains a controversial topic. Although low serum thyroid hormone concentrations have been associated with acute laminitis in some horses, it is unlikely that decreased thyroid function alone causes laminitis. In five studies in which hypothyroidism was induced either by surgical removal of the thyroid glands or by administration of propylthiouracil, laminitis did not occur.[92–96] Therefore any alterations in serum thyroid hormone concentrations in horses experiencing laminitis may be caused by factors associated with the episode of laminitis, rather than being the cause of the laminitis itself. Such factors could include drugs used to treat laminitis (e.g., phenylbutazone), development of nonthyroidal illness syndrome, or a direct effect of proinflammatory mediators that may contribute to the onset of laminitis.

In the author's experience, TRH stimulation tests performed in a horse that has had an episode of laminitis or that has had bouts of recurrent laminitis show normal thyroid hormone responses when these tests are performed after the horse is stabilized and has been off all medications for 4 weeks.

Despite evidence of normal thyroid function in horses with laminitis, some veterinary clinicians still believe that treatment of horses with iodinated casein during an acute episode of laminitis results in improvement. These horses often are treated without prior measurement of thyroid hormones. Some are treated even when measurement shows serum thyroid hormone concentrations to be within the normal range. These horses are then often kept on thyroid hormone supplementation indefinitely. To date, no controlled studies have been performed to determine whether or not administration of thyroid hormones during acute episodes of laminitis is beneficial. However, because the action of α-adrenergic agonists on vasculature is usually vasodilatory, it is possible that thyroid hormone administration increases circulation to the foot by its ability to potentiate α-adrenergic receptor numbers and sensitivity.[119–121] It is also possible that thyroid hormone supplementation alters carbohydrate and fat metabolism in a way that increases insulin sensitivity.[118] Thus, any beneficial effect of thyroid hormone administration in horses with laminitis may be pharmacologic rather than physiologic.

41.1.3.3.4.3

ANHIDROSIS

Anhidrosis is a condition of adult horses characterized by a decreased ability or inability to sweat in response to appropriate stimuli. The cause is unknown. Hypothyroidism has long been associated with anhidrosis, perhaps because treatment with iodinated casein was reported to help increase sweat production in anhidrotic horses in the 1950s.[122] However, the author found that baseline concentrations of thyroid hormones and TSH were normal in horses with anhidrosis.[123] Thyroid hormone responses to TRH were also normal, but TSH responses to TRH were significantly greater in anhidrotic horses than they were in horses with normal sweat production. The clinical significance of this exaggerated TSH response in anhidrotic horses is unknown. It is possible that any observed benefit of thyroid hormone supplementation is pharmacologic, rather than physiologic as was suggested for laminitis. Because equine sweat glands are stimulated to secrete by activation of β_2-adrenergic receptors and because thyroid hormones modulate adrenergic receptor function, perhaps making horses mildly hyperthyroid iatrogenically restores β-adrenergic receptor numbers or sensitivity or potentiates sweat responses to whatever neural stimulation remains.

41.1.3.3.4.4

RHABDOMYOLYSIS

A link between hypothyroidism and rhabdomyolysis was suggested by a report of muscle stiffness, poor performance, and rhabdomyolysis in four thoroughbred and two standardbred racehorses that had low baseline T_4 concentrations.[124] The horses improved after administration of iodinated casein. However, T_4 response to TSH was normal in these horses. A subsequent study showed normal resting concentrations of T_4 but decreased T_4 response to TRH in five horses that had previous episodes of rhabdomyolysis.[125] In a study of 18 quarter horses with polysaccharide storage myopathy and 18 thoroughbreds with recurrent exertional rhabdomyolysis, circulating concentrations of T_4 and T_3 were within normal range. Stimulation tests were not performed.[126] Therefore a role for hypothyroidism in the pathophysiology of equine rhabdomyolysis is unclear. Because it is now known that the clinical syndrome of rhabdomyolysis can be caused by more than one underlying pathophysiologic entity, it is

possible that hypothyroidism may contribute to some but not all cases of equine rhabdomyolysis. If hypothyroidism is suspected, thyroid function should be ideally assessed by measuring both resting concentrations of free thyroid hormones and response to TRH or TSH. If resting concentrations of free thyroid hormones are found to be low, nonthyroidal factors should be ruled out before thyroid hormone supplementation is prescribed.

41.1.3.3.4.5

INFERTILITY IN MARES

1349

Thyroid hormone administration to broodmares has been a fairly common practice, despite lack of evidence that the mares were actually hypothyroid in the first place or that thyroid hormone supplementation improves fertility of horses. This practice presumably is an extrapolation from human medicine, where hypothyroidism in women adversely affects fertility. However, Lowe and colleagues reported that two of three fillies that had undergone thyroidectomy became pregnant without thyroid hormone supplementation,[92] and two recent publications showed no association between thyroid hormone status and conception rates.[127,128] The first study was performed in 329 clinically normal broodmares.[127] Resting serum T_4 concentrations were below normal in 12% of the mares, normal in 86%, and increased in 6%. There was no association between serum T_4 concentration and whether or not the mare was pregnant 15 to 16 days after ovulation. There also was no association between whether or not the mare was receiving thyroid hormone supplementation (60 were, 269 were not) and pregnancy status. In the second study, resting serum concentrations of total T_4 and T_3, as well as their responses to TRH, were measured in 79 thoroughbred and standardbred broodmares.[128] Resting and stimulated thyroid hormone concentrations were not different between mares that became pregnant and mares that did not.

1350

Although these studies suggest there is no association between thyroid status and fertility or infertility in the mare, it is still possible that hypothyroidism contributes to infertility in a small subset of mares and that this effect is being lost among all the other potential causes of failure to conceive. However, given that true hypothyroidism appears to very rare in the horse, this would have to be a very small number of mares—certainly not as many mares as are currently being routinely supplemented. Is there any basis, then, to the clinical impression held by some that thyroid hormone supplementation helps some mares get pregnant? If there is, perhaps it is more related to obesity, IR, and EMS than to hypothyroidism. Women with IR and metabolic syndrome are subfertile, and there is evidence that thyroid hormone administration to normal-weight mares increases insulin sensitivity.[118] Therefore it is possible that insulin-resistant, overweight mares are subfertile, and thyroid hormone supplementation is beneficial not because the mares were hypothyroid but because it improves their insulin sensitivity. At the time of this writing, no studies have been performed to examine this hypothesis.

41.1.3.3.5

Assessment of Thyroid Function in Adult Horses

Because certain drugs and pathophysiologic states can lower serum concentrations of thyroid hormones in otherwise euthyroid horses, it is important that thyroid function tests not be performed while horses are ill, receiving certain drugs, or on thyroid hormone supplementation. The author recommends that thyroid hormone testing be performed in horses that have not received any medications for at least 2 and preferably 4 weeks before testing. If a horse has been receiving thyroid hormone supplementation without prior documentation of hypothyroidism, the author recommends weaning the horse off supplementation and then testing thyroid function once the horse has not received any supplementation for at least 4 weeks.

Tests that are currently available for assessment of thyroid function in the horse include measurement of total and free fractions of T_4 and T_3 and response of these hormones to administration of either TRH or TSH.[98–100,125,129–132] Although results of TRH or TSH stimulation tests are thought to provide a better indication of thyroid status than single-point-in-time measurements of thyroid hormone concentrations, these tests are not routinely performed by ambulatory clinicians because of the impracticality of having to take multiple blood samples over time. In addition, TRH and TSH either are not readily available commercially for sterile, single-dose application or are prohibitively expensive.

For performance of a stimulation test, a control blood sample is obtained, TRH (1 mg to the average 450- to 500-kg horse) or TSH (5 IU) is given intravenously (IV), and subsequent blood samples are obtained. Most references say that T_3 should double at 2 hours and T_4 should double at 4 hours. The author routinely performs TRH stimulation tests and prefer to measure both T_3 and T_4 before and 1, 2, and 4 hours after TRH administration, in order to make sure the peaks are not missed. In 36 normal horses that participated in various studies the author conducted, the mean increase in total T_4 was 2.2 times at 4 hours. However, the range was 1.3 to 3.8 times. Increases in free T_4 and free T_4 by dialysis (mean and range) were 1.7 (1.1 to 2.1) times and 1.8 (1.1 to 2.8) times at 4 hours, respectively. Increases in total and free T_3 (mean and range) were 3 (1.1 to 10.3) times and 4.2 (1 to 53) times at 2 hours, respectively. These seemingly lower thyroid hormone responses to TRH injection are in agreement with findings in a recent report of levothyroxine administration to normal horses.[133] Closer examination of the data from the author's horses revealed that in general the few individuals with small increases in T_4 or T_3 either started with higher resting values or had peaks that occurred later (T_4) or earlier (T_3) than 4 or 2 hours. Individuals with lower T_4 responses in general were not the same individuals with lower T_3 responses. Therefore one must be careful when interpreting results of a TRH stimulation test. Failure of T_3 to double by 2 hours or T_4 to double by 4 hours after TRH injection does not necessarily mean that the horse is hypothyroid. Individuals with high responses tended to be individuals with very low resting thyroid hormone concentrations.

If single-point-in-time measurement of thyroid hormones is the only option available for evaluation of thyroid status, measurement of free fractions of thyroid hormones (alone or in conjunction with measurement of total amounts of hormone) provides more useful information than measurement of total amounts of thyroid hormones alone. Measurement of serum TSH concentration in single samples will likely aid diagnosis of thyroid status once a TSH assay for the horse becomes commercially available.

During illness in humans, measurement of serum free T_4 by direct methods often underestimates values when compared with measurements of free T_4 after dialysis or ultrafiltration.[134–138] This also appears to be the case in dogs[139] and horses.[106] Therefore serum concentrations of free T_4 measured by equilibrium dialysis are more likely to reflect true thyroid status in ill horses, compared with other methods of free T_4 measurement. Measurement of fT_4D instead of fT_4 may help prevent equine clinicians from misdiagnosing ill horses as being hypothyroid.

41.1.3.3.6

Treatment of Hypothyroidism in Adult Horses

Management of horses that have been properly diagnosed as being hypothyroid or horses that have undergone thyroidectomy theoretically should be fairly straightforward. Serum thyroid hormone concentrations should be monitored and dosages of thyroid hormone supplementation adjusted to maintain

serum thyroid hormones in the normal range. This is not necessarily as simple as it sounds. T_4 is the most common form of thyroid hormone supplementation. T_4 administration increases serum concentrations of T_4; however, serum concentrations of T_3 may not change or may actually decrease if T_3 is not also given or if the horse is not truly hypothyroid. In addition, T_4 dosage recommendations have been made based on thyroid hormone concentrations obtained after thyroid administration to normal horses with intact thyroid glands.[140] Thyroid hormone pharmacokinetics may be different in truly hypothyroid horses; pharmacokinetic studies in horses made hypothyroid by thyroidectomy or by administration of antithyroid drugs would be useful. Until such studies are performed, the following recommendations can be made. T_4 is available in several forms. Iodinated casein contains approximately 1% T_4 and is given at 5 to 15 g/horse/day by mouth [PO].[92] The recommended starting dose of levothyroxine was 20 g/kg/day PO,[82,140] but a more recent study suggested that doses as high as 50 to 100 g/kg/day are well tolerated and may be necessary.[133] If a sensitive TSH assay becomes commercially available, dosages should be adjusted to normalize TSH.

1350
1351

41.1.3.4 THYROID FUNCTION IN NORMAL NEONATAL FOALS

Fetal concentrations of T_3 and cortisol are low.[141] In many species fetal serum thyroid hormones increase just before birth and probably play a role in the rapid growth and organ system development that occur in late gestation. Normal neonatal foals have serum concentrations of thyroid hormones that are approximately 10 times adult concentrations.[142–144] Thyroid hormones remain very high during the first week of life, then slowly decline, reaching normal adult concentrations by approximately 1 month of age. These high concentrations of thyroid hormones are thought to be important in maintaining thermogenesis, regulation of cell differentiation, and maturation of many body systems, especially the respiratory, nervous, and musculoskeletal systems. Thyroid hormones increase thermogenesis by increasing metabolic rate and, of particular relevance to the neonate, increasing heat production from brown fat.[145] Thyroid hormones also stimulate lung development and surfactant production, and these effects are potentiated by concurrent administration of glucocorticoids.[146] Skeletal growth and maturation are stimulated synergistically by thyroid hormones and growth hormone (GH).[147] The mechanisms by which thyroid hormones are increased in the peripartum period are unknown. One might expect the increase to be centrally driven. However, in a study the author recently completed,[144] serum TSH concentrations were not increased in equine neonates compared with adults, nor did they change over the first month of life while serum thyroid hormone concentrations were declining.

41.1.3.4.1 Thyroid Function in Premature Foals

Premature human infants experience transient hypothyroxinemia, with serum T_4 concentrations correlated to gestational age.[148–151] In a study recently conducted by the author, serum concentrations of thyroid hormones and TSH at rest and in response to TRH were measured in foals to determine the possible contributions of an immature hypothalamic-pituitary axis and nonthyroidal illness to thyroid function. Three groups of foals were examined: (1) normal, healthy neonatal foals that were full term and not receiving any medications (normal foals); (2) premature neonatal foals (premature foals); and (3) full-term neonatal foals that were hospitalized for conditions similar to those encountered in premature foals (sick foals).[144] Both sick and premature foals received medications routinely used to treat their conditions, which included (but were not limited to) failure of passive transfer, sepsis, and perinatal asphyxia

syndrome. Blood samples were collected for measurement of baseline concentrations of total and free thyroid hormones and TSH at predetermined ages. TRH stimulation tests were performed in foals at less than 3 days of age. Premature foals had significantly lower serum concentrations of total and free fractions of thyroid hormones than normal foals. Baseline serum concentrations of TSH were not different, but TSH responses to TRH were exaggerated in premature foals compared with normal foals. Serum concentrations of T_3 and TSH were similar in sick full-term foals and premature foals, but serum concentrations of T_4 in sick full-term foals were intermediate between those of premature and normal foals. These results suggest that sick foals experience nonthyroidal illness syndrome, primarily a low T_3 state. The effects of drugs commonly used to treat ill foals on serum thyroid hormone concentrations in the premature and sick foals in this study were not examined. More profound alterations in thyroid function in premature foals compared with sick full-term foals may be caused by an immature hypothalamic-pituitary-thyroid axis. It remains to be seen whether early thyroid hormone supplementation in premature foals might improve short-term survivability and preserve long-term athletic function. Traditional thought has been that administration of thyroid hormones to patients with nonthyroidal illness syndrome is not beneficial and might even be detrimental. However, these beliefs have recently been challenged,[109,110] and the issue remains controversial. Although results are variable, treatment of premature human infants with T_4 has resulted in improved IQ and neurologic development at 2 years of age,[148,149] and T_3 administration to human neonates with severe respiratory distress syndrome has been shown to improve survival.[152]

41.1.3.4.2

Congenital Hypothyroidism in Foals

Two syndromes of congenital hypothyroidism have been described in foals. Hypothyroid foals with visible goiters have been produced by mares ingesting either too much or too little iodine and by mares ingesting goitrogenic plants.[153–155] These foals are born weak, with poor sucking and righting reflexes, hypothermia, and developmental abnormalities of the musculoskeletal system, including tendon contracture or rupture and delayed bone development, particularly of the small cuboidal bones of the carpus and tarsus. Thyroid hormone supplementation to more severely affected foals may improve survivability, but dosage recommendations are scarce. Irvine recommends basing the dose on secretion rate.[147] For oral administration of T_4, this would equal 10 × 0.22 × kilograms of body weight × 0.08 × plasma T_4 (g/L). This calculates to approximately 2.5 mg/day PO for a 1- to 3-day-old 50-kg foal. Because there is a time delay for T_4 to act and because T_3 is more active than T_4, T_3 supplementation at one third the calculated T_4 dose may provide more benefit initially.

A second syndrome of congenital hypothyroidism has been described in foals, primarily in the western parts of the United States and Canada.[156–160] This syndrome is characterized by thyroid gland hyperplasia, increased gestational length, and musculoskeletal abnormalities, including mandibular prognathia, flexural limb deformities of the front legs, ruptured digital extensor tendons, and incomplete ossification of the carpal and tarsal bones. Despite the prolonged gestation, other indicators of prematurity may be present, such as a silky hair coat. At the time of birth, baseline serum concentrations of T_4 and T_3 are usually within the normal neonatal ranges, but the response to TSH administration is decreased.[161] The cause is unknown but suspected to be a dietary deficiency or toxicity of the mare during gestation. Likely candidates include nitrate, low iodine, low selenium, or goitrogenic plant ingestion by the mare.[159,161] Because thyroid hormone concentrations are normal at the time of birth, thyroid hormone supplementation is usually not administered. Supportive care to try to prevent collapse of the carpal and tarsal bones is recommended.

41.1.4 EQUINE METABOLIC SYNDROME

NICHOLAS FRANK

41.1.4.1 Definitions

Equine metabolic syndrome (EMS) is characterized by obesity or regional adiposity, IR, and subclinical or clinical laminitis. Regional adiposity occurs in the form of adipose tissue accumulation in the neck or tailhead region, and subclinical laminitis is detected by the presence of abnormal growth rings (also called *founder lines*) on the hooves. The term *equine metabolic syndrome* has been adopted because IR and regional adiposity are components of metabolic syndrome in humans. However, EMS is unique to this species because other components of metabolic syndrome, including abdominal adiposity, hypertension, and microalbuminemia, have not been detected in horses.[162,163] The term *prelaminitic metabolic syndrome* (PLMS) has also been introduced to describe ponies at risk for developing pasture-associated laminitis because of IR.[164] This is sometimes referred to as *endocrinopathic laminitis* because of its association with IR in horses and ponies.

Obesity is defined as an increase in body weight because of excessive fat accumulation within the body. When the body condition score (BCS) system developed by Henneke and colleagues[165] is applied, obesity is defined by a BCS ≥7 on a 1 (poor) to 9 (extremely fat) scale. Obesity and IR are associated in horses and ponies.[166,167] *Insulin resistance* refers to the failure of insulin-sensitive tissues to respond to insulin. Skeletal muscle, adipose, and liver tissues are primarily affected because they are the primary sites for insulin-mediated glucose disposal. Hyperinsulinemia is a feature of compensated IR, whereas uncompensated IR occurs when beta-cell insufficiency (pancreatic failure) develops. Compensated IR is more common in horses and ponies, but uncompensated IR sometimes accompanies advanced PPID. Type 2 diabetes mellitus occurs when hyperglycemia develops as a result of uncompensated IR. *Diabetes* actually refers to excessive production of urine (polyuria), which is caused by glucosuria in the case of diabetes mellitus. There has been a recent report of diabetes mellitus in a Spanish Mustang,[168] but this condition is rare in horses.

41.1.4.2 Etiology

Genetic predisposition plays an important role in the development of obesity and IR in horses. Ponies tend to be more insulin resistant than horses,[167] and certain breeds of horse including Morgan horses, Arabians, and Norwegian Fjords appear to more predisposed to obesity and IR.[162,166] Horses with this predisposition are sometimes referred to as “easy keepers” because they require fewer calories to maintain body weight. Environmental factors including diet and exercise are also likely to play important roles in the development of obesity and IR in horses. Feeding concentrates to a susceptible animal is often enough to induce obesity and the grass consumed on pasture can be a significant source of calories. Carbohydrate intake on pasture is influenced by grazing time, the area grazed, and the water-soluble carbohydrate (WSC) and starch content of pasture grasses. Amounts of these carbohydrates vary considerably by geographic location, climate, soil quality, and season.[169] Exercise increases insulin sensitivity in humans and horses, so more sedentary horses may be more susceptible to obesity.[170,171] EMS affects adult horses, and most affected animals are over 5 years of age. There is no identifiable sex predilection.

41.1.4.3

Clinical Signs and Differential Diagnoses

Obesity is detected on physical examination of the horse and application of a BCS system. A mare with EMS is shown in Fig. 41-10. Regional adiposity is commonly detected in horses with IR, and mean neck circumference has been negatively correlated with insulin sensitivity in obese horses with IR.[166] The technique for measuring mean neck circumference is presented in Fig. 41-11. Expansion of adipose tissues within the neck is commonly referred to as a "cresty neck," and with the exception of stallions this finding is suggestive of IR in horses. Enlarged fat deposits may also be found close to the tailhead, within the sheath, or randomly distributed as subcutaneous swellings. Abnormal fat deposits may also develop in older horses with PPID but are usually accompanied by hirsutism, loss of skeletal muscle mass, polyuria, or polydipsia.[172] Horses with EMS commonly have laminitis, which is detected by observing the horse's gait or applying hoof testers to the feet. Some horses do not show signs of laminitis on physical examination but have a history of previous disease. Others have abnormal growth rings (founder lines) or radiographic evidence of third-phalanx rotation or sinking. IR predisposes ponies to pasture-associated laminitis,[164] and there is anecdotal evidence to suggest that the same association exists in horses.

41.1.4.4

Clinical Pathology

1352

Complete blood count and serum biochemical analysis results are usually unremarkable, except blood glucose concentrations are sometimes toward the upper end of the reference range. Hyperglycemia is more commonly detected in ponies. It occasionally occurs in horses with PPID and may be accompanied by mature neutrophilia with lymphopenia. Elevated serum triglyceride concentrations may be detected in ponies[164] or horses[166] with obesity and IR, but this finding is inconsistent in our experience. Plasma concentrations of VLDL and high-density lipoprotein cholesterol (HDL-C) are significantly higher in obese horses with IR, but these measurements are not readily available.[166]

1353

Low resting total triiodothyronine (tT_3) or total thyroxine (tT_4) concentrations are sometimes detected in obese horses with IR, but the significance of this finding has been overstated in the past. It is a common misconception that obese horses have hypothyroidism because obesity is associated with hypothyroidism in dogs and humans. However, advanced testing rarely supports a diagnosis of hypothyroidism in horses with EMS. Serum thyroid hormone concentrations rise appropriately when TRH is injected intravenously, indicating that the hypothalamic—pituitary gland—thyroid gland axis is functioning normally. It is therefore likely that serum thyroid concentrations reflect responses to extrathyroidal changes in metabolism. Breuhaus and co-workers[173] recently detected markedly lower serum tT_4 and free T_4 concentrations in horses with

systemic illness, and these values were below the reference ranges used by most laboratories. Results of that study illustrate that extrathyroidal factors lower serum thyroid hormone concentrations, which may lead to the incorrect diagnosis of primary hypothyroidism. Phenylbutazone also significantly lowers serum tT_4 concentrations in horses, and this drug is commonly used to treat laminitis in horses with EMS.[174]

41.1.4.5

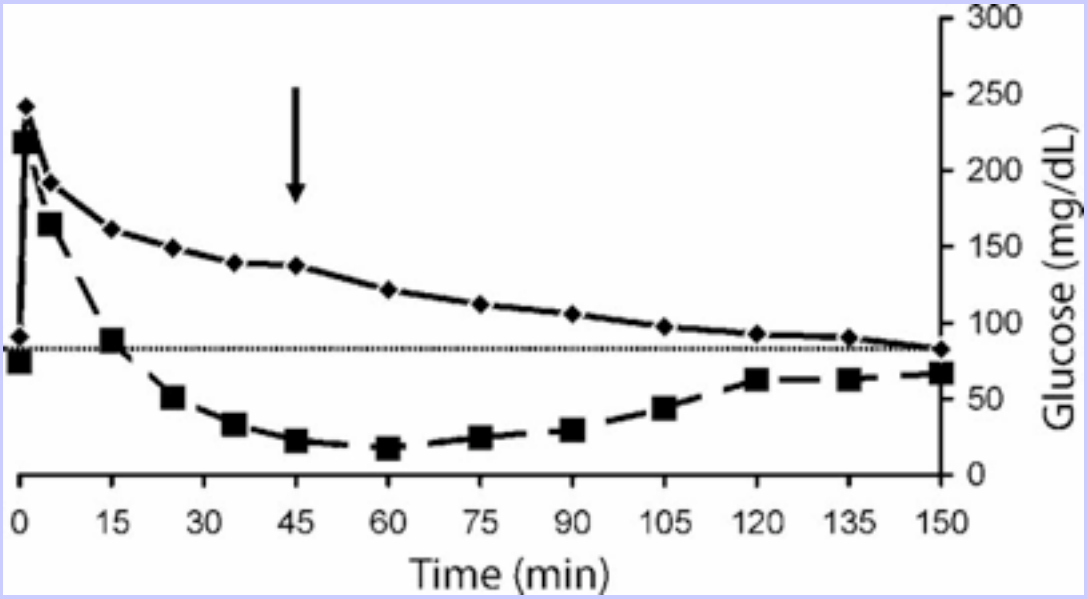
Diagnostic Testing

Horses can be screened for IR by measuring resting serum insulin concentrations. Results should be interpreted using the reference range provided by the laboratory. In our laboratory a resting serum insulin concentration above 20 μU/mL is suggestive of IR, and a concentration above 30 μU/mL defines hyperinsulinemia. Resting serum insulin concentrations can be measured to screen horses for IR and assess responses to diet or exercise, but it should be recognized that this diagnostic test does not detect uncompensated IR. Grass consumed on pasture and concentrates can potentially elevate serum insulin concentrations, so it is important to remove horses from pasture and feed only grass hay for a minimum of 24 hours (and ideally 72 hours) before collecting blood samples.

Two proxies have recently been established to provide measures of insulin sensitivity and pancreatic beta-cell function in horses and ponies.[175] The reciprocal of the square root of insulin (RISQI) measurement uses the resting serum insulin concentration and provides a measure of insulin sensitivity, whereas serum concentrations of both glucose and insulin are used to calculate the modified insulin-to-glucose ratio (MIRG), which represents the pancreatic beta-cell response. Horses with compensated IR have a low RISQI and high MIRG, whereas both the RISQI and MIRG are low in horses with uncompensated IR.

The combined glucose-insulin test (CGIT) is a useful field test for detecting IR in horses.[166] This test involves collection of a baseline blood sample followed by intravenous infusion of 150 mg of 50% dextrose solution per kilogram of body weight, then immediately by 0.10 unit of regular insulin per kilogram of body weight.[176] Blood samples are collected at 1, 5, 15, 25, 35, 45, 60, 75, 90, 105, 120, 135, and 150 minutes postinfusion. When the CGIT is used, IR is defined as maintenance of blood glucose concentrations (measured with a hand-held glucose meter) above the baseline (preinjection) value for 45 minutes or longer (Fig. 41-12). The test can be abbreviated to 60 minutes when used in the field, but it is advisable to complete the measurements so that the time taken for the blood concentration to return to baseline can be recorded for future reference. This allows responses to diet, exercise, or medications to be assessed. There is a small risk of inducing hypoglycemia when this test is performed, so two 60-mL syringes containing 50% dextrose should be kept on hand and administered if muscle fasciculations or profound weakness are observed or if the blood glucose concentration drops below 40 mg/dL. Note that stress is an important cause of transient IR that can significantly affect CGIT results. In one study, IR was detected in healthy nonobese horses when CGIT procedures were performed immediately after endoscopic examinations.[176] Horses must therefore remain calm before and during the procedure to avoid false-positive results. An intravenous catheter should ideally be placed the night before testing to minimize stress. Because pain affects results, horses with acute laminitis must be given time to recover before testing is performed. Feed deprivation also causes stress, so horses are permitted to eat grass hay during the testing procedure.

Fig. 41-12 Blood glucose concentrations during the combined glucose-insulin test (CGIT) in a healthy nonobese mixed-breed horse *(dashed line)* and an obese insulin-resistant Morgan horse mare *(solid line)*. The horizontal line represents the approximate baseline plasma glucose concentration, and the arrow indicates the time point (45 minutes postinjection) selected to define insulin resistance when the CGIT is used. Blood concentrations remain above the baseline value for 45 minutes or longer if the horse is insulin resistant.



41.1.4.6

Pathophysiology

Relationships among obesity, IR, and laminitis in horses are complex. It is likely that certain horses are genetically predisposed to obesity and IR and these animals are recognized by their owners as easy keepers. Adipose tissues expand as obesity develops, through an increase in adipocyte size (hypertrophy) or number (hyperplasia). This appears as generalized obesity and/or regional adiposity, and either may be accompanied by IR. In horses, regional adiposity increases the size of adipose tissues within the nuchal crest, and neck circumference has been negatively correlated with insulin sensitivity in obese insulin-resistant horses.[166] Fat thickness over the rump has also been used as a measure of body fat mass in horses,[177] and some affected animals develop pronounced fat pads in this area. It has been suggested that visceral adipose tissues play an important role in the development of IR because expansion of visceral fat depots is a feature of metabolic syndrome in humans. This syndrome is caused by increased 11β-HSD activity and excessive local cortisol production within visceral adipose tissues.[162] However, insulin sensitivity has not been correlated with visceral fat mass in horses, and no evidence presented to date has supported an association between IR and

altered 11β-HSD activity in this species. Regional adiposity may simply reflect an altered metabolic state in IR horses. 1354

Horses that are evolutionarily adapted to sparse forages and harsher conditions may be predisposed to obesity because lipid accumulates more readily when excessive calories are provided in the diet. A state of overnutrition may be induced when genetically predisposed horses are turned out on lush pastures. The natural equine diet contains little fat, but excess glucose can be converted into fat via de novo lipogenesis. Fats are used for energy or stored as triglyceride within cells. When the storage capacity of adipose tissues is exceeded, fats are directed toward nonadipose tissues (repartitioning). Skeletal muscle, liver, and pancreatic tissues attempt to use fats by increasing beta oxidation, but lipid can accumulate within these tissues and alter normal cellular functions. This pathophysiologic condition is sometimes referred to as *lipotoxicity*.[178] Reactive oxygen species are also generated as oxidative pathways are upregulated. Oxidant damage contributes to lipotoxicity and lipid-induced programmed cell death (lipoapoptosis). Inflammation accompanies these events, resulting in the release of TNF-α and IL-6 from adipose tissues. Adipocytes can also release proinflammatory cytokines referred to as *adipokines* that act locally or enter the blood. IR develops when these events affect insulin-sensitive adipose, liver, and skeletal muscle tissues. Insulin receptors or their downstream signaling pathways are disrupted, which lowers insulin sensitivity. More insulin is released from the pancreatic beta cells to compensate for the reduction in insulin sensitivity, which results in compensatory hyperinsulinemia.

Associations between laminitis and insulin sensitivity require further study, but results of in vitro studies suggest that equine hoof keratinocytes have a high requirement for glucose and dermoepidermal attachments are weakened when the availability of glucose is reduced.[179,180] IR is also likely to affect vascular dynamics within the foot because insulin serves as a slow vasodilator and recruits capillaries to the local circulation.[181] Insulin stimulates the release of the vasodilator nitric oxide from vascular endothelial cells, and this process is inhibited when IR develops.[181] It is therefore conceivable that dietary exacerbation of IR, including intracellular lipid accumulation and the generation of inflammatory mediators, causes parallel impairment of metabolic and vascular responses, which significantly reduces nutrient delivery to hoof tissues.

41.1.4.7

Management

The principal components of management are exercise and diet. Horses that are free of overt laminitis should be ridden or exercised on a lunge line each day. Although laminitic horses should not be exercised during the acute phase of the disease, hand walking may be beneficial once the condition stabilizes.

Weight loss should be induced in obese horses by restricting the total number of calories consumed. In horses that are being overfed, removal of all concentrates from the diet is often sufficient to achieve the ideal body weight. Total caloric intake should initially be met by feeding grass hay exclusively in amounts equivalent to 1.5% to 2% of current body weight (e.g., 18 to 24 lb of grass hay per day for a 1200-lb horse). If the horse does not lose weight, the amount fed should be lowered over several weeks to 1.5% of ideal body weight (e.g., 15 lb of grass hay for an ideal weight of 1000 lb). These strategies are effective for horses kept in stalls or dirt paddocks, but weight loss is more difficult to achieve when horses are grazing on pasture. Strategies for limiting grass consumption on pasture include shortened turnout time, confinement to a small paddock, round pen, or area enclosed with electric fence, or use of a grazing muzzle.

When managing horses with EMS, close attention must be paid to the amount of sugar consumed in the diet. Concentrates such as sweet feed should be eliminated altogether because they tend to be rich in readily

available sugar. However, forages can also be a concern if they contain large amounts of hydrolyzable carbohydrate in the form of starch or fermentable carbohydrate such as fructans, which are polymers of fructose.[182] Hay samples should be submitted to a forage laboratory for analysis. Laboratories provide values for WSC (simple sugars and fructans) and starch or collectively report these components as nonstructural carbohydrate (NSC). Structural carbohydrates include cellulose and lignin, which are measured as neutral detergent fiber (NDF).[182] Insulin-resistant horses should ideally be fed grass hay containing less than 12% NSC, and clients should be encouraged to analyze each batch of hay before purchasing. If hay with a higher NSC content must be fed, soaking in water for 30 minutes will leach out some soluble sugars.[183] Pasture grass also provides large quantities of NSC that can exacerbate IR and increase the likelihood of laminitis.[164] Grass growing on pasture varies in NSC content according to location, soil type, rainfall, season, and time of day.[169] It is therefore advisable to restrict or eliminate access to pasture when managing horses with EMS. If grazing is permitted, pasture grass samples should ideally be collected from different pastures at various times of the year to determine the best location and safest time for grazing affected horses.

Insulin-resistant horses that exhibit regional adiposity but have a thinner overall body condition are more difficult to manage because additional calories must be provided without exacerbating IR. Some of these horses are affected by PPID, and others have lost weight through regular exercise but remain insulin resistant. Diets rich in fat and fiber increase insulin sensitivity in horses, whereas feeds rich in starch and sugar have the opposite effect.[184] It is therefore advisable to select low-sugar feeds such as molasses-free beet pulp and add vegetable oil to provide additional calories. Commercial feeds containing more fat and fiber are also available, and these feeds may be appropriate for thinner horses with IR. However, these feeds are not recommended for obese horses; these animals require only grass hay and an appropriate vitamin and mineral supplement.

Some horses with EMS that have repeated episodes of laminitis must be removed from pasture altogether. These horses should be kept in dirt paddocks and fed only grass hay and a vitamin and mineral supplement. After weight loss has been achieved, reintroduction to pasture can be attempted. However, some horses are so sensitive to alterations in pasture nutrient content that they must be held off pasture permanently in order to avoid pasture-associated laminitis. Grazing in the early morning is likely to be safer for horses with IR, except after a hard frost, when grasses rapidly accumulate sugars.[185]

Levothyroxine sodium can be administered to accelerate weight loss when treating an obese horse that cannot be exercised, when obesity persists despite dietary interventions, or if the horse has repeated episodes of laminitis. It has previously been demonstrated that levothyroxine sodium (Thyro-L, Lloyd, Inc., Shenandoah, Iowa) lowers body weight and improves insulin sensitivity in horses.[186] Levothyroxine can be administered orally or in the feed at a dose of 4 tsp (48 mg) per day until the ideal body weight is achieved or for up to 6 months. When treatment is discontinued, the dosage should be lowered to 2 tsp (24 mg)/day for 2 weeks and then 1 tsp (12 mg)/day for 2 weeks. Health problems have not been associated with the administration of levothyroxine to horses for 12 months, but the 4 tsp (48 mg)/day dose should not be exceeded, and treatment at this higher dose should not extend beyond 6 months. In the past, levothyroxine has been inappropriately prescribed to horses for extended or lifelong treatment of hypothyroidism. As described here, levothyroxine is used for a defined period of time to induce weight loss presumably by increasing basal metabolic rate.

1354
1355

Numerous other treatments have been proposed for the management of IR in horses including magnesium supplementation, chromium,[187] clenbuterol,[188] and cinnamon. Each of these therapies may be of benefit, but further studies are required to establish their efficacy in the management of EMS.

41.1.5 PARATHYROID GLAND AND CALCIUM DYSREGULATION

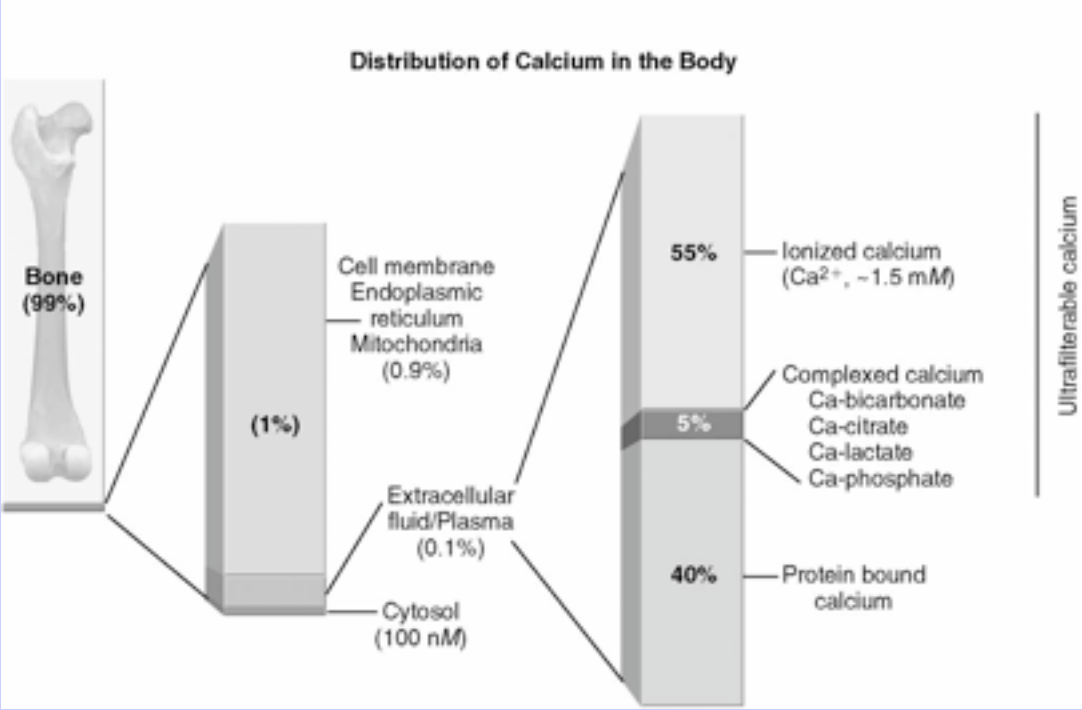
Ramiro E. Toribio

41.1.5.1 CALCIUM

Calcium is the fifth most abundant element in the body, representing approximately 1.5% of the body weight. Physiologic functions such as muscle contraction, hormone secretion, enzyme activation, cell division, cell membrane stability, neuromuscular excitability, and blood coagulation are calcium-dependent.[189] Processes that result in cell injury and death such as free radical production, cytokine release, protease activation, vasoconstriction, and apoptosis also depend on calcium.

Calcium has structural and nonstructural functions, and it is found in three main compartments: the skeleton, soft tissues, and extracellular fluid. The skeleton contains approximately 99% of the total body calcium (and 80% of phosphorus) as hydroxyapatite ($Ca_{10}[PO_4]_6[OH]_2$) in a calcium:phosphorus ratio of 2:1. As part of the skeleton, calcium provides support against gravity, protects vital internal organs, and houses blood-forming elements. The skeleton also acts as a reservoir for calcium. The nonstructural functions are related to calcium as a regulatory ion. The remaining calcium is present in the cell membrane, mitochondria, endoplasmic reticulum, and extracellular fluid.[189] In blood, most calcium is in plasma in a free or ionized form (approximately 55%), bound to proteins (approximately 40%), and complexed to anions such as citrate, bicarbonate, phosphate, and lactate (approximately 5%) (Fig. 41-13).[189–191] In horses, serum ionized calcium represent 50% to 55% of the total serum calcium.[191–193] Free, unbound, or ionized calcium (Ca^{2+}) is the biologically active form of calcium. Of the protein-bound calcium, approximately 80% is associated with albumin and 20% with globulins. Calcium binds to negatively charged or anionic proteins. This affinity is pH dependent. During acidosis, increased H^+ concentrations decrease Ca^{2+} binding to anions, resulting in increased plasma Ca^{2+} concentrations. Alkalosis lowers Ca^{2+} concentrations. Hypoalbuminemia results in total hypocalcemia (pseudohypocalcemia), with Ca^{2+} concentrations remaining within the normal range.

Fig. 41-13 Calcium distribution in the body.[190] Approximately 99% of the total body calcium is in the skeleton. The remaining calcium is present in the cell membrane, mitochondria, endoplasmic reticulum, and extracellular fluid. In blood, calcium exists in a free or ionized form (Ca^{2+}), bound to proteins, and complexed to anions such as citrate, bicarbonate, phosphate, and lactate. In horses, serum Ca^{2+} represents 50% to 55% of the total serum calcium concentration.



Calcium and phosphorus requirements in horses depend on age, physiologic status, and amount of work or exercise performed (Table 41-1). Serum Ca^{2+} concentrations are not a reliable indicator of dietary calcium intake. An acceptable diet for horses must have 0.15% to 1.5% of calcium and 0.15% to 0.6% of phosphorus in feed dry matter (Box 41-1). A calcium:phosphorus ratio less than 1:1 can have negative effects on calcium absorption and skeletal development; however, a calcium:phosphorus ratio as high as 6:1 for growing horses may not be detrimental if phosphorus intake is adequate.[194] Adult horses should receive approximately 40 mg of calcium/kg/day (see Table 41-1). Average horses must absorb 20 to 25 mg of calcium and 10 to 12 mg of phosphorus/kg/day to meet their needs and balance losses. Calcium and phosphate content in some mineral supplements and equine feeds are presented in Tables 41-2 and 41-3.

Horses have distinctive features with regard to calcium metabolism. These include high serum total and ionized calcium concentrations,[193] poorly regulated intestinal Ca^{2+} absorption,[195] high urinary fractional

excretion of calcium,[193] low serum concentrations of vitamin D metabolites,[196] and decreased parathyroid gland sensitivity to Ca^{2+}.[197,198]

1355

1356

Most calcium absorption occurs in the small intestine.[195,199] Compared with other species, horses absorb a larger proportion of dietary calcium. Horses can absorb 50% to 75% of the calcium and less than half the phosphorus in their diet, with little effect of age.[195] Calcium absorption is inversely related to dietary calcium content. High content of phosphate (or phytate, oxalate) inhibits calcium absorption; however, high dietary calcium content has minimal effect on phosphorus absorption. Oxalates reduce calcium absorption. Some plants containing harmful amounts of oxalate are listed in Table 41-4. The dietary cation-anion balance (DCAB) affects Ca^{2+} absorption in horses; a low DCAB increases intestinal Ca^{2+} absorption, whereas a high DCAB has the opposite effect.[200] Glucocorticoids decrease intestinal absorption of calcium, decrease bone resorption, and increase urinary excretion of Ca^{2+} in horses.

Table 41-1 Calcium and Phosphorus Requirements in Horses[249]

	Percent in the Diet		Daily Intake (grams)	
	Ca	P	Ca	P
Foals (<6 months)	0.80	0.55	33	20
Weanlings	0.60	0.45	34	25
Yearlings	0.50	0.35	31	22

Calcium is eliminated through the kidneys, milk, sweat, feces, and fetus. In the kidney approximately 60% of calcium is reabsorbed in the proximal tubules by passive mechanisms, and 35% is reabsorbed in the thick ascending loop of Henle and distal tubules by active mechanisms. The rest (approximately 5%) represents the urinary fractional excretion of calcium. Endogenous losses of calcium in horses have been estimated to be 20 to 25 mg/kg of body weight per day. Assuming a 50% calcium digestibility, a 500-kg horse would require 20 g of calcium to replace losses, or 40 mg/kg/day; growing and lactating horses can double these requirements. 1356 1357 Interpretation of the urinary excretion of calcium can be difficult because horses eliminate large amounts of calcium (primarily calcium carbonate) in urine.[190]

Sugar beet	*Beta vulgaris*

* These plants have an oxalate content higher than 0.5% of dry matter, or a calcium:oxalate ratio of <0.5.

Calcium deficiency can be acute or chronic. Horses with acute calcium deficiency have clinical signs associated with neuromuscular excitability. Chronic calcium deficiency in general is manifested as abnormal cartilage and bone development (developmental orthopedic disease [DOD]) and lameness. When calcium deficiency is suspected, feed analysis is recommended to determine if dietary calcium and phosphorus are adequate.

41.1.5.2

PHOSPHORUS

In blood, phosphorus exists as organic (intracellular) and inorganic (extracellular) phosphates. Organic phosphate consists of phosphate esters (phospholipids) bound to proteins and blood cells and represents most of the phosphorus in circulation; however, only inorganic phosphate (PO_4) is measured. PO_4 is found as ionized phosphate (approximately 50%), complexed with cations (Na^+, Ca^{2+}, Mg^{2+}; approximately 35%), and bound to proteins (approximately 15%). At pH 7.4, PO_4 exists as divalent (HPO_4^{2-}) and monovalent ($H_2PO_4^-$) anions in a 4:1 ratio. In acidosis this ratio is 1:1, and it can be as high as 9:1 during alkalosis.[201] In soft tissues, most of the phosphate is organic, intracellular, and incorporated into nucleic acids, phospholipids, and energy compounds such as adenosine triphosphate (ATP) and creatine phosphate. Phosphate is important for muscle contraction; neurologic functions; enzyme activity; electrolyte transport; oxygen transport (2,3-diphosphoglycerate [DPG]); intermediary metabolism of proteins, carbohydrates, and fats, gene transcription, and cell proliferation and differentiation. Approximately 80% of the PO_4 is in the skeleton bound to calcium as hydroxyapatite. PO_4 regulation is closely associated with Ca^{2+} homeostasis.

Phosphorus requirements depend on age, physiologic status, and amount of work or exercise performed (see Table 41-1). In horses, phosphorus absorption ranges from 30% to 55% and occurs in the small and large intestines.[195,202] High aluminum in the diet reduces phosphorus absorption. In the kidneys, most of the PO_4 is reabsorbed in the proximal tubules by an Na^+-dependent mechanism, and the urinary fractional excretion of PO_4 in horses is low (<0.5%).

Chronic excess of phosphorus results in clinical signs consistent with calcium deficiency including lameness, abnormal cartilage and bone development, fractures, and osteodystrophia fibrosa (nutritional secondary hyperparathyroidism). Acute renal failure and hypoparathyroidism are associated with hyperphosphatemia. Conditions that result in cell lysis such as hemolysis, rhabdomyolysis, and tumor necrosis may cause acute hyperphosphatemia.

Hypophosphatemia occurs from inadequate intake, decreased intestinal absorption, renal waste, hyperparathyroidism, sepsis, and intracellular shift. Intracellular PO_4 shift is a common cause of hypophosphatemia in critically ill humans and small animals and occasionally occurs in horses with starvation or refeeding syndrome or receiving parenteral nutrition (hyperglycemia, hyperinsulinemia). Acute hypophosphatemia is associated with cell membrane fragility and lysis (hemolysis, rhabdomyolysis). Chronic phosphate deficiency can be manifested as weight loss, weakness, pica (depraved appetite), lameness, and DOD. Rickets, as described in other species with PO_4 or vitamin D deficiency, is not a recognized condition in foals. Serum PO_4 concentration is more indicative of dietary phosphorus intake and status than serum Ca^{2+} because PO_4 homeostasis is not as precise as that of Ca^{2+}. Normal PO_4 concentrations are presented in Table 41-5.

Table 41-5 Normal Serum Concentrations in Healthy Horses

Variable	Concentration
Total calcium (mg/dL)	11.1–13
Ionized calcium (mg/dL)	6–7
Phosphorus (mg/dL)	1.2–4.8

* Measured in ethylenediaminetetraacetic acid (EDTA) plasma. FE_{Ca}, Urinary fractional excretion of calcium; FE_P, urinary fraction excretion of phosphorus; *PTH*, parathyroid hormone; *PTHrP*, PTH-related protein.

41.1.5.3

CALCIUM AND PHOSPHORUS HOMEOSTASIS

Extracellular ionized calcium (Ca^{2+}) concentrations are regulated by a homeostatic system that includes three hormones (parathyroid hormone [PTH], calcitonin, and 1,25-dihydroxyvitamin D_3[$1,25(OH)_2D_3$]; calcitriol); three body systems (kidney, intestine, and bone); and a calcium-sensing receptor (CaR).[190,193,203] PTH increases during hypocalcemia and hyperphosphatemia, whereas calcitonin increases during hypercalcemia (Fig. 41-14). Under physiologic conditions PTH-related protein (PTHrP), which also activates the PTH-1 receptor, has little effect on Ca^{2+} homeostasis.[204] PO_4 is closely associated with Ca^{2+} homeostasis. The role of phosphatonins, which inhibit renal PO_4 reabsorption and $1,25(OH)_2D_3$ synthesis, is unknown in the horse.[205]

PTH is secreted by the chief cells of the parathyroid gland in response to hypocalcemia and hyperphosphatemia. Parathyroid chief cells detect changes in Ca^{2+} concentrations by a CaR.[197,206] Through the PTH receptor, PTH increases renal Ca^{2+} reabsorption (distal nephron), decreases renal PO_4 reabsorption (proximal tubules), stimulates renal calcitriol synthesis (proximal tubules), and stimulates osteoclastic bone resorption (see Fig. 41-14). Calcitriol then increases intestinal absorption and renal reabsorption of Ca^{2+} and

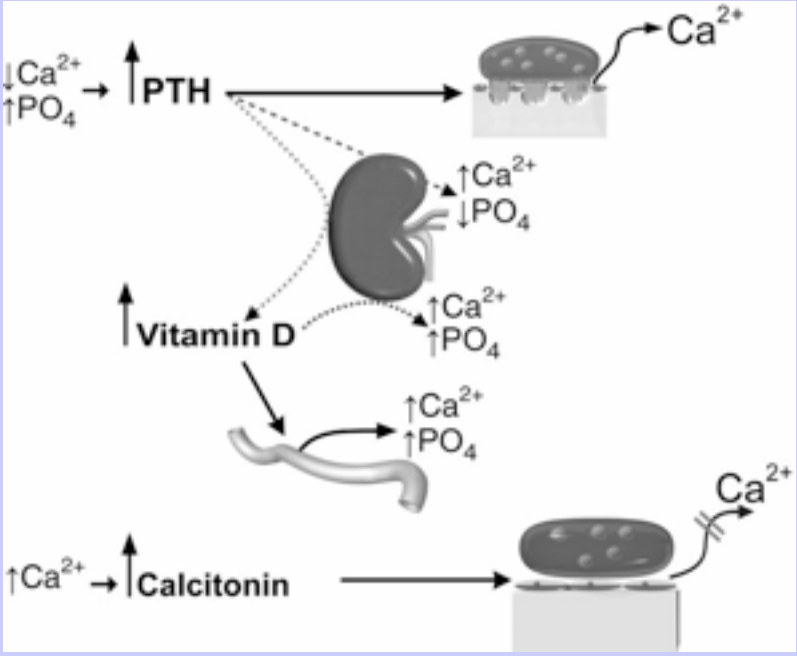
PO_4 and inhibits PTH synthesis and secretion.[190] PTH secretion is under the influence of Ca^{2+}, PO_4, and vitamin D. Biologically active intact PTH is measured with immunometric assays.

Vitamin D plays an important role in Ca^{2+} and PO_4 homeostasis and to lesser extent in magnesium metabolism. Vitamin D_2 (ergocalciferol) and vitamin D_3 (cholecalciferol) are secosterols derived from photolytic cleavage of the B rings of ergosterol (plants and yeasts) and 7-dehydrocholesterol (animals), respectively. Vitamin D_3 is hydroxylated in the liver to produce 25-hydroxyvitamin D_3 [$25(OH)D_3$; calcidiol], which is transported to the kidney to produce the active metabolite 1,25-dihydroxyvitamin D_3 [$1,25(OH)_2D_3$; calcitriol] by 1α-hydroxylase. In mammalians, 25(OH)D is the major circulating form of vitamin D. Hypocalcemia, hypophosphatemia, and PTH stimulate $1,25(OH)_2D$ synthesis by inducing renal 1α-hydroxylase activity, whereas hypercalcemia, hyperphosphatemia, and increased $1,25(OH)_2D$ concentrations inhibit 1α-hydroxylase.

1357

1358

Fig. 41-14 Calcium and phosphate homeostasis. A decrease in serum Ca^{2+} or increase in serum PO_4 concentrations increases PTH secretion. PTH increases renal Ca^{2+} reabsorption and vitamin D synthesis, decreases renal PO_4 reabsorption, and increases osteoclastic bone resorption. In turn, vitamin D increases intestinal absorption and renal reabsorption of Ca^{2+} and PO_4. On the contrary, hypercalcemia decreases PTH secretion and stimulates calcitonin secretion to inhibit osteoclastic bone resorption.



Vitamin D stimulates intestinal absorption and renal reabsorption of Ca^{2+} and PO_4. $1,25(OH)_2D$ increases the expression and activity of proteins important for transcellular Ca^{2+} transport, including epithelial Ca^{2+} channels, Ca^{2+} binding proteins (calbindin D_{9k}, calbindin D_{28k}), Na^+/Ca^{2+} exchangers, and Ca^{2+} -ATPases. The effects of $1,25(OH)_2D$ on intestinal absorption and renal reabsorption of PO_4 are mediated by Na^+ -PO_4 cotransporters. In addition, $1,25(OH)_2D$ increases Mg^{2+} renal reabsorption.[207] In bone, $1,25(OH)_2D$ increases bone matrix synthesis and mineralization and stimulates osteoclastic activity and bone resorption. In the parathyroid gland, $1,25(OH)_2D$ inhibits PTH synthesis and secretion.[208] Vitamin D deficiency results in rickets in young animals and osteomalacia in adults; however, the existence of rickets in the horse is not clearly documented.

Calcitonin is a 32—amino acid peptide secreted by the parafollicular cells (C cells) of the thyroid gland in response to hypercalcemia. Calcitonin inhibits osteoclast function and bone resorption and decreases renal reabsorption of Ca^{2+} and PO_4 in most species. There is limited information on calcitonin in the horse.[209]

PTHrP is produced by almost every tissue in the body and has a broad range of functions that have little to do with Ca^{2+} homeostasis.[204] Under physiologic conditions, PTHrP functions (morphogenesis, cell differentiation) are considered to be paracrine, autocrine, and intracrine. For the most part, the endocrine functions are considered pathologic (humoral hypercalcemia of malignancy [HHM]). HHM is a paraneoplastic syndrome that results from excessive secretion of PTHrP by some tumors. By interacting with PTH receptors, PTHrP promotes bone resorption and inhibits renal Ca^{2+} excretion, causing hypercalcemia in humans and domestic animals, including the horse.[210–215]

Organs involved in Ca^{2+} homeostasis (parathyroid gland, thyroid gland, and kidney), known as the *calcium-sensing system,* express a CaR, which is a G protein—coupled seven transmembrane domain receptor that is activated by extracellular Ca^{2+} and to lesser affinity by Mg^{2+}.[206] CaR activation inhibits PTH secretion and stimulates calcitonin secretion in various species, including the horse.[197,198] In the kidney, CaR regulates Ca^{2+} and Mg^{2+} reabsorption independently of PTH. Renal CaR activation inhibits the furosemide-sensitive $Na^+/K^+/2Cl^-$ cotransporter in the distal nephron, resulting in diuresis and urinary waste of Ca^{2+} and Mg^{2+}.[206]

41.1.5.4

CALCIUM DISORDERS IN THE HORSE

Calcium dysregulation in the horse is associated with hypocalcemic and hypercalcemic disorders. Equine pathologic conditions characterized by abnormal calcium homeostasis include hypoparathyroidism,[216,217] primary hyperparathyroidism,[218] nutritional secondary hyperparathyroidism,[219] renal failure,[220] HHM,[211,212,214] vitamin D toxicity,[221] exercise-induced hypocalcemia,[222] idiopathic hypocalcemia of foals,[223] cantharidiasis,[224] and sepsis.[193,225,226] Normal calcium concentrations for horses are presented in Table 41-5.

41.1.5.4.1

Hypocalcemic Disorders

Conditions associated with hypocalcemia in the horse are presented in Box 41-2. Most clinical signs of hypocalcemia are the result of increased neuromuscular excitability and decreased smooth muscle cell contractility (Box 41-3). A decrease in extracellular Ca^{2+} concentrations increases cell membrane Na^{+} permeability, decreasing the resting membrane potential, thus making muscle cells and nerve fibers more excitable. This results in spontaneous and continuous discharges, muscle fasciculations, tremors, tetany, and seizures. Tachycardia and cardiac arrhythmias may be present, although bradycardia may develop during severe hypocalcemia. Decreased serum ionized magnesium (Mg^{2+}) concentration occurs frequently in horses with hypocalcemia and further increases neuromuscular excitability.

Synchronous diaphragmatic flutter (SDF) or "thumps" may occur in horses with hypocalcemia associated with gastrointestinal disease,[193] endurance exercise,[227] hypoparathyroidism,[217,228] idiopathic hypocalcemia,[223] tetany (lactation, transport),[229] sepsis,[193] blister beetle toxicosis,[230] and alkalosis.[190] SDF develops when depolarization of the right atrium stimulates action potentials in the phrenic nerve as it crosses over the heart. Clinically, affected animals have a rhythmic movement on the flank from diaphragmatic contractions that are synchronous with the heartbeat.

During alkalosis there is increased Ca^{2+} binding to albumin, resulting in ionized hypocalcemia. Exercising horses may develop alkalosis from hyperventilation (respiratory alkalosis) and chloride losses in the sweat (metabolic hypochloremic alkalosis). Hypomagnesemia is common in horses with SDF and hypocalcemia.

Hypocalcemic tetany is the development of sustained skeletal muscular contractions in horses with hypocalcemia. Although hypocalcemic tetany can occur in any horse with hypocalcemia, lactating mares and horses transported for long distances are at greatest risk. Lactation tetany may occur anytime in mares immediately before foaling up to the end of the lactation period. In particular, mares producing large amounts of milk and eating diets low in calcium, grazing lush pastures, or performing physical work (draft mares) are at risk. Clinical signs may include anxiety, depression, ataxia, muscle fasciculations and tremors, stiff gait, tachypnea, dyspnea, dysphagia, hypersalivation, and hyperhidrosis (see Box 41-3).[190]

Hypocalcemic seizures, seen in foals and adult horses, are caused by decreased CNS extracellular Ca^{2+} concentrations leading to increased neuronal excitability. Clinical signs usually improve with calcium treatment, although some animals may require repeated treatments. In general, horses and foals with refractory hypocalcemic seizures have a poor prognosis for recovery.

Ileus and retained placenta in mares are both believed to result from decreased smooth muscle tone and contractility secondary to hypocalcemia. Whereas in skeletal muscle most of the Ca^{2+} required for contraction comes from the sarcoplasmic reticulum, in smooth muscle Ca^{2+} comes from the extracellular space. For this reason, any condition that results in hypocalcemia can decrease smooth muscle contractility. Retained placenta in mares has been reported to occur in up to 10% of foalings.[231]

Hypoparathyroidism in horses is characterized by hypocalcemia, hyperphosphatemia, hypomagnesemia, and decreased serum PTH concentrations. Primary hypoparathyroidism results from decreased secretion of PTH, whereas secondary hypoparathyroidism results from magnesium depletion and sepsis. There are few documented cases of primary hypothyroidism in horses.[217,228] Hypoparathyroidism should be suspected in any horse or foal with refractory hypocalcemia. Clinical signs include ataxia, seizures, hyperexcitability,

SDF, tachycardia, tachypnea, muscle fasciculations, bruxism, stiff gait, recumbency, ileus, and colic.[190,217,228] Laboratory findings include hypocalcemia, hyperphosphatemia, and low or normal serum intact PTH concentrations. Hypomagnesemia may be present in some horses and foals.[217,228] Secondary (functional or acquired) hypoparathyroidism per se has not been reported in the horse; however, some critically ill foals and horses with hypocalcemia have impaired parathyroid gland function, which we believe represents hypoparathyroidism secondary to sepsis and/or hypomagnesemia.

Critically ill foals may develop a form of hypocalcemia that is refractory to calcium treatment.[223] These foals have low or normal PTH concentrations despite hypocalcemia, suggesting hypoparathyroidism. This condition has been called *neonatal idiopathic hypocalcemia*.[223] It is believed that abnormal parathyroid gland function may result from increased inflammatory cytokines. IL-1 and IL-6 have been shown to increase CaR activation and decrease PTH secretion by equine parathyroid cells.[197] Prognosis for survival in foals with refractory hypocalcemia is poor.

Sepsis and endotoxemia are the most common cause of hypocalcemia in equine patients admitted to veterinary hospitals. Clinical observations also indicate that hypocalcemia is common in horses with severe gastrointestinal disease.[193] Hypocalcemia in septic patients often results from parathyroid gland dysfunction (insufficient PTH secretion) as well as intracellular calcium sequestration.[190,193] Inflammatory mediators known to be increased in horses and foals with sepsis and endotoxemia such as TNF-α, IL-1, and IL-6 decrease equine parathyroid cell sensitivity to Ca^{2+} and PTH secretion.[197]

Horses under intense exercise develop electrolyte and acid-base abnormalities. Unlike humans, who may develop either hypocalcemia or hypercalcemia, hypocalcemia is a more consistent finding throughout exercise in the horse. Exercise-induced hypocalcemia may result from Ca^{2+} losses in the sweat, intracellular movement of Ca^{2+}, increased Ca^{2+} binding to albumin, lactate, phosphate, and bicarbonate during alkalosis, and parathyroid gland dysfunction.[222]

Oxalate toxicity causes hypocalcemia by interfering with calcium absorption; a diet consisting of 1% oxalate or higher can reduce most intestinal calcium absorption.[232] It is important that the equine diet contain less than 0.5% oxalate or a calcium:oxalate ratio over 1.0. Clinical signs associated with oxalate excess are those of phosphate excess, calcium deficiency, and nutritional hyperparathyroidism. Oxalates are present in several grasses and toxic plants (see Table 41-4).

Equine cantharidiasis (blister beetle toxicosis) is a condition reported in the southwestern and midwestern United States and results from the ingestion of alfalfa contaminated with beetles (*Epicauta* species) that produce cantharidin (cantharidic acid). Clinical signs develop from the irritant effects of cantharidin on mucosal surfaces (gastrointestinal and urinary tracts). Cantharidin often causes acute hypocalcemia and hypomagnesemia. Therefore clinical signs of severe hypocalcemia (muscle fasciculations, SDF, ataxia, dyspnea, laryngeal spasm, and cardiac arrhythmias) may be present. It is unclear why these horses develop hypocalcemia; however, it may be a combination of severe gastrointestinal disease associated with acute renal failure and parathyroid gland dysfunction.

1359
1360

Hypocalcemia and hypomagnesemia are common findings in horses with acute renal failure. Reabsorption of Ca^{2+} and Mg^{2+} in the kidney is highly dependent on functional epithelial cells, and these cells are very susceptible to various insults (hypoxia, ischemia, toxins). The loss of epithelial cells and their absorptive capacity results in decreased reabsorption of Ca^{2+} and Mg^{2+}.

The pathogenesis of hypocalcemia in exertional rhabdomyolysis is unknown. It is speculated that damage to muscle fibers during intense exercise results in Ca^{2+} influx and sequestration in the sarcoplasmic reticulum.

41.1.5.4.1.3

TREATMENT OF HYPOCALCEMIA

Calcium deficit, maintenance, losses, and sequestration should be considered when treating hypocalcemia. If parathyroid gland function is normal, minimal to no calcium supplementation may be required. Most horses with hypocalcemia do not show overt signs of hypocalcemia. Lack of therapy, however, can result in development of additional complications, in particular ileus. Horses with functional kidneys can rapidly eliminate large amounts of calcium, and hypercalcemia from excessive calcium administration is rare, particularly if the horse is receiving fluid therapy. When possible, calculate the calcium deficit based on Ca^{2+} concentrations (mg/dL = mmol/L × 4). From a practical standpoint, the use of standard formulas for electrolyte deficit can be used (multiplied by 10, as calcium is expressed as mg/dL). Total calcium can be used to estimate calcium deficit, keeping in mind that total calcium has more variability than Ca^{2+} concentration, as it is dependent on plasma protein concentration. A horse can have total hypocalcemia, but serum Ca^{2+} concentrations may be within the normal range (pseudohypocalcemia), and calcium administration may not be necessary. It is also important to remember that 9.3% of calcium gluconate is elemental calcium, which means that a 23% solution of calcium gluconate contains 2.14% of elemental calcium or 21.4 mg/mL. Avoid the use of calcium chloride, as it can cause subcutaneous irritation.

Frequent monitoring of Ca^{2+} concentration and adjustment of dosage are important. Rapid administration of calcium may result in cardiovascular complications, especially in horses with sepsis, which may be more vulnerable to the toxic effects of calcium. In our experience, horses can handle high calcium doses. For an average size horse with mild hypocalcemia (5 mg/dL), we administer 50 mL of 23% calcium gluconate per 5 L of crystalloid fluids at a fluid rate twice maintenance. Oral treatment with calcium salts is feasible in some horses with non—life-threatening, refractory hypocalcemia. Dicalcium phosphate and calcium carbonate (limestone, 200 to 300 g/day) can be used safely (see Table 41-2).

41.1.5.4.2

Hypercalcemic Disorders

Hypercalcemic disorders in horses are divided into two groups: (1) parathyroid gland—dependent hypercalcemia (develops because of parathyroid gland hyperfunction), and (2) parathyroid gland—independent hypercalcemia (develops despite parathyroid gland suppression). This distinction is clinically relevant in the differential diagnosis and in the interpretation of specific diagnostic tests, including intact PTH, PTHrP, Ca^{2+}, PO_4, and vitamin D concentrations. Parathyroid gland—dependent hypercalcemia in the horse is limited to primary hyperparathyroidism, whereas parathyroid-independent hypercalcemia results from various conditions (secondary hyperparathyroidism, chronic renal failure [CRF], hypercalcemia of malignancy, and hypervitaminosis D).

Primary hyperparathyroidism results from an excessive and autonomous synthesis and secretion of PTH by the parathyroid gland that is not responsive to the negative feedback of Ca^{2+}. Primary hyperparathyroidism has been reported in ponies and horses[218,233–236] and results from parathyroid

adenomas or parathyroid hyperplasia. The elevated PTH concentrations increase renal Ca^{2+} reabsorption, decrease PO_4 reabsorption, increase $1,25(OH)_2D_3$ synthesis, and increase bone resorption (osteodystrophia fibrosa). Laboratory findings include hypercalcemia, hypophosphatemia, hypocalciuria, and hyperphosphaturia. PTHrP concentrations are within normal limits (low or undetectable). Clinical findings include facial bone enlargement, lameness, and a poor body condition. Radiographic findings include decreased long and facial bone density, fibrous proliferation of the maxilla and mandible, and loss of the lamina dura surrounding the molars.[218] Endoscopic examination may reveal narrowing of the nasal passages.

Postmortem findings include enlargement of the maxilla and mandible, stenosis of the nasal passages, and loosening of premolars and molars. Histologic evaluation of the parathyroid gland is important to confirm the diagnosis of primary hyperparathyroidism; however, finding the parathyroid glands in the horse is a challenge because of their small size and variable location.[190] Although not documented in horses, treatment consists of surgical removal of the affected parathyroid gland.

Secondary hyperparathyroidism is characterized by excessive secretion of PTH in response to hyperphosphatemia and hypovitaminosis D from chronic renal failure (renal secondary hyperparathyroidism) or hyperphosphatemia and/or hypocalcemia from nutritional imbalances (nutritional secondary hyperparathyroidism). Renal secondary hyperparathyroidism is not a well recognized disease in the horse. Unlike humans and small animals, in which CRF results in hyperphosphatemia, horses with CRF often have hypophosphatemia. Moreover, the hypercalcemia in horses with CRF is the result of renal Ca^{2+} retention rather than increased PTH concentrations. The increased Ca^{2+} concentrations in turn decrease PTH secretion; therefore PTH concentrations in horses with CRF frequently are below or within the normal range.[216,237] In contrast, nutritional secondary hyperparathyroidism is a well documented pathologic condition of the horse.

41.1.5.5

NUTRITIONAL SECONDARY HYPERPARATHYROIDISM

41.1.5.5.1

Definition and Etiology

Horses fed diets low in calcium, high in phosphorus, or with a phosphorus:calcium ratio of ≥3:1 may develop nutritional secondary hyperparathyroidism, also known as *bran disease, Miller's disease, big head, osteodystrophia fibrosa, osteitis fibrosa,* and *equine osteoporosis*.[234] Pastures and toxic plants with high content of oxalates (see Table 41-4) predispose to secondary hyperparathyroidism.

41.1.5.5.2

Pathogenesis

Excessive dietary PO_4 reduces intestinal calcium absorption and results in hyperphosphatemia. Dietary oxalates form insoluble calcium oxalate ($Ca[COO]_2$), reducing calcium absorption. Both high-phosphorus and low-calcium diets induce parathyroid cell hyperplasia and stimulate PTH secretion in the horse.[234] Hyperphosphatemia directly stimulates PTH secretion and inhibits renal $1,25(OH)_2D$ synthesis. Because $1,25(OH)_2D$ inhibits parathyroid cell proliferation, low $1,25(OH)_2D$ concentrations contribute to parathyroid cell hyperplasia and PTH secretion. Hyperphosphatemia also results in the formation of calcium phosphate precipitates, reducing blood Ca^{2+}, and inducing additional PTH secretion. PTH increases osteoclastic activity, bone resorption, and bone loss (Fig. 41-15).[238] There is facial bone loss

1360 1361

with excessive accumulation of subperiosteal unmineralized connective tissue (osteodystrophia fibrosa) resulting in facial enlargement (big head) (Fig. 41-16). Because this is a condition of slow progression, the homeostatic mechanisms that regulate extracellular Ca^{2+} concentrations (PTH, vitamin D, calcitonin) in general are effective in maintaining Ca^{2+} within the normal range. Affected horses preserve normocalcemia at the expense of the skeletal reserves and do not develop clinical signs of acute hypocalcemia.

41.1.5.5.3

Clinical Signs

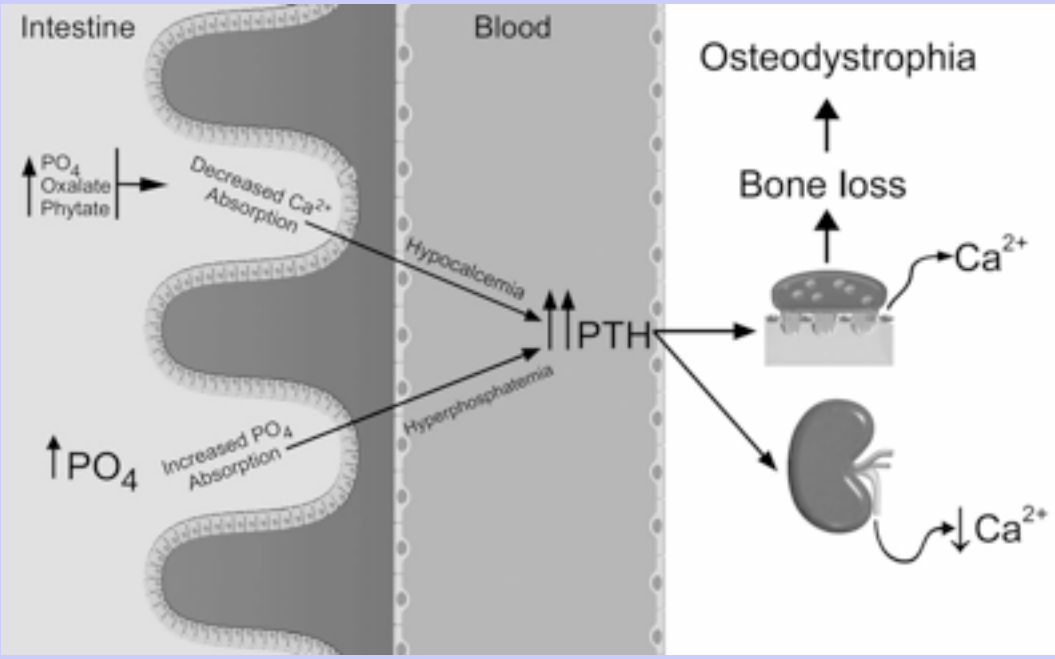
Clinical signs result from increased bone resorption and include unthriftiness, intermittent, shifting lameness, and a stiff gait. Younger animals may develop physitis and limb deformities. There is a typical and symmetric swelling of the facial bones; however, facial bone enlargement may not be evident in old horses (see Fig. 41-16). The facial changes and the increased bone resorption around molars and premolars may result in masticatory problems. These horses are physically weak and may be in poor body condition from the pain associated with lameness and mastication. In severe cases, teeth may become loosened and spontaneous fractures of long bones may occur. Upper airways obstruction, dyspnea, and epiphora may be present.[239,240]

41.1.5.5.4

Laboratory Findings

Typical laboratory changes in horses with nutritional secondary hyperparathyroidism include hyperphosphatemia, hypocalcemia or normocalcemia (hypercalcemia is unusual), and increased intact PTH concentrations, especially if the animal is eating a low-calcium or high-phosphorus diet at the time of evaluation. The urinary fractional excretion of calcium is low (hypocalciuria), whereas the excretion of phosphorus is increased (hyperphosphaturia). Serum alkaline phosphatase activity and collagen degradation products may be increased. Laboratory findings may be within normal limits if the animal is eating a balanced diet.

Fig. 41-15 Pathogenesis of nutritional secondary hyperparathyroidism in horses. Excessive dietary phosphorus reduces intestinal absorption of calcium and induces hyperphosphatemia. In addition, phosphate, oxalate, and phytate bind dietary calcium to reduce absorption. Both high-phosphorus and low-calcium diets induce parathyroid cell hyperplasia and stimulate PTH secretion. PTH increases osteoclastic activity and bone resorption, resulting in bone loss (osteodystrophia fibrosa).



41.1.5.5.5

Radiologic Findings

Decreased bone density is frequent; however, bone density must be decreased by 30% before it can be detected radiographically.[241] Decreased facial bone density along with fibrous proliferation is a consistent finding. Resorption of alveolar sockets and loss of the dental lamina dura may be present before other radiographic changes are present, and long bones are affected only in advanced cases.

41.1.5.5.6

Necropsy

There is increased bone resorption, bone fragility, accumulation of fibrous tissue around facial bones, obstruction of nasal passages, and parathyroid gland hyperplasia (see Fig. 41-16). Soft-tissue mineralization has been reported in affected foals.[241a]

41.1.5.5.7

Treatment

Diet evaluation is indicated. Eliminate or reduce any grain-based diet and avoid high-containing oxalate feeds. The addition of alfalfa to the diet may be helpful. Supplementation with calcium carbonate (limestone; $CaCO_3$) or dicalcium phosphate may result in improvement.[219] Ground limestone, which contains no phosphorus, is recommended as a good source of calcium (35%). An affected animal may require a total of 100 to 300 g/day. The diet should have a Ca:P ratio of 3:1 or 4:1. Limestone may decrease feed palatability, and adding molasses should be considered. Supplementation with vitamin D has been proposed. Horses may require 9 to 12 months for complete recovery, although some bone changes may not regress. Confinement of severely affected horses is advised. The use of NSAIDs may be indicated in some animals.

1361

1362

Fig. 41-16 Big head. Two-year-old Belgium horse presented to the Ohio State University Veterinary Teaching Hospital with clinical signs consistent with nutritional secondary hyperparathyroidism, including facial bone enlargement and upper respiratory noise. The horse was fed excessive amounts of grain. There was narrowing of the nasal passages, loss of bone mass, and excessive accumulation of unmineralized bone matrix (osteodystrophia fibrosa) in maxillary and mandibular bones.

41.1.5.6 # HYPERVITAMINOSIS D

41.1.5.6.1 ## Definition and Etiology

The ingestion or administration of ergocalciferol (vitamin D_2) or cholecalciferol (vitamin D_3) results in disturbances of calcium and phosphorus metabolism in horses.[221,242–244] Ingestion of plants containing 1,25$(OH)_2$D-like compounds results in typical clinical signs of vitamin intoxication.[243,245] The ingestion of *Solanum glaucophyllum (Solanum malacoxylon)* results in a condition known as "enteque seco" in Argentina and "espichamento" in Brazil.[242,245] In Hawaii, *Solanum sodomaeum,* and in the southern United States, jessamine *(Cestrum diurnum)* may cause hypervitaminosis D.[243] In Europe the ingestion of golden oat *(Trisetum flavescens)* results in enzootic calcinosis.

41.1.5.6.2 ## Pathogenesis

Hypervitaminosis D increases the intestinal absorption and renal reabsorption of calcium and phosphorus. Hyperphosphatemia is the most consistent and early laboratory finding in horses with vitamin D intoxication.[246] Serum calcium concentrations may be increased or within the normal range.[221,243,244] Hypervitaminosis D results in parathyroid cell atrophy and decreased PTH secretion. In addition, hypercalcemia contributes to decreased PTH secretion, lowering bone turnover. Azotemia and hyposthenuria may be present.[221]

41.1.5.6.3 ## Clinical Signs

Most clinical findings in horses with hypervitaminosis D are the result of hyperphosphatemia. Affected horses often have weight loss, poor appetite, lameness, and painful stiffness and are reluctant to move. Acute death from severe cardiovascular mineralization has been reported.[221] Polyuria and polydipsia are frequent findings. In cases with hypercalcemia, mineral deposition in the kidneys may precede mineralization elsewhere, resulting in renal failure. Lameness is probably caused by calcification of ligaments and tendons.

41.1.5.6.4 ## Radiologic Findings

These horses often have increased bone density, decreased size of the medullary cavity, and increased calcification of soft tissues.

41.1.5.6.5 ## Treatment

Reducing dietary calcium intake and using calcium-binding agents such as sodium phytate have been proposed.[244] Glucocorticoids are used in humans with hypervitaminosis D, as they may inhibit the vitamin D—mediated intestinal calcium absorption. In equids, glucocorticoids decrease intestinal absorption of calcium, increase urinary excretion of calcium, and decrease bone resorption.[190] Dexamethasone has been administered to horses with hypervitaminosis D with variable results. The prognosis for horses with hypervitaminosis D is poor.

1362 1363

41.1.5.6.6

Necropsy Findings

Postmortem examination may reveal mineralization of soft tissues. Mineralization of the endothelium of the aorta and pulmonary vessels and of the endocardium is frequent. Mineralization may be found in the kidney, liver, lymph nodes, lungs, ligaments, and tendons. Osteopetrosis of epiphyses and metaphyses may be present. Atrophy of the parathyroid gland can be severe.[247]

41.1.5.7

HYPERCALCEMIA OF MALIGNANCY

HHM (pseudohyperparathyroidism) is a paraneoplastic condition in which humans and animals develop hypercalcemia associated with various types of tumors. These malignancies secrete PTHrP, which interacts with PTH receptors to increase renal reabsorption of Ca^{2+} and bone resorption.[248] In horses, HHM has been associated with squamous cell carcinoma, adrenocortical carcinoma, lymphosarcoma, multiple myeloma, and ameloblastoma.[190] Laboratory findings include hypercalcemia, hypocalciuria, hypophosphatemia, hyperphosphaturia, normal or low PTH concentrations, and increased PTHrP concentrations. HHM should be suspected in any horse with hypercalcemia, no evidence of renal disease, and normal PTH concentrations.

Table 41-6 Normal Equine Reference Values and SI Conversion Factors

Variable	Normal Range	Conversion
Total calcium	11.1–13 mg/dL*	mmol/L = mg/dL × 0.25
Ionized calcium	6–7 mg/dL*	mmol/L = mg/dL × 0.25
Phosphorus	1.2–4.8 mg/dL*	mmol/L = mg/dL × 0.323
Total magnesium	0.53–0.91 mmol/L*	mg/dL = mmol/L × 2.43
Ionized magnesium	0.46–0.66 mmol/L*	mg/dL = mmol/L × 2.43
PTH	1–4 pmol/L*	pg/mL = pmol/L × 9.5
Calcitonin	<40 pg/mL*	pmol/L = pg/mL × 0.29
PTHrP	<1 pmol/L*	pg/mL = pmol/L × 10
25-Vitamin D_3	See text	nmol/L = ng/mL × 2.5
1,25-Vitamin D_3	See text	pmol/L = pg/mL × 2.4
Glucose	89–112 mg/dL†	mmol/L = mg/dL × 0.05551
Insulin	<300 pmol/L† <30 μIU/mL‡	μIU/mL = pmol/L × 0.1296

41.1.5.8 NEONATAL HYPERCALCEMIA AND ASPHYXIA

Clinical observation indicates that a number of critically ill newborn foals develop hypercalcemia associated with peripartum asphyxia. The mechanisms underlying this problem are unknown, although it is speculated to be associated with placental insufficiency.

41.1.5.9 TREATMENT OF HYPERCALCEMIA

Hypercalcemia as an equine emergency is rarely presented; however, the differential diagnosis of hypercalcemia is important for its treatment. Few disorders in the horse are associated with hypercalcemia (hyperparathyroidism, CRF, HHM, hypervitaminosis D). Mild to moderate hypercalcemia in general is not life-threatening, and treatment should be directed to the primary cause. Although unreported, parathyroidectomy is the treatment of choice for primary hyperparathyroidism. Surgical removal of epithelial tumors can be a successful treatment for HHM. Some horses with lymphosarcoma may show improvement with chemotherapy. In severe cases of hypercalcemia that may require medical treatment, initial therapy should include the administration of a 0.9% saline solution and loop diuretics. Furosemide is the diuretic of choice because it inhibits the $Na^+/K^+/2Cl^-$ contransporter in the distal tubules, increasing the urinary excretion of calcium. Thiazide diuretics are contraindicated because they stimulate calcium reabsorption. Glucocorticoid administration should be considered, in particular for horses with hypervitaminosis D.

41.1.6 BOVINE METABOLIC DISORDERS

41.1.6.1 KETOSIS OF RUMINANTS (ACETONEMIA)

SHERRILL A. FLEMING

41.1.6.1.1 Definition

Ketosis is a condition characterized by abnormally elevated concentrations of ketone bodies in the body tissues and fluids.[253] The ketone bodies are acetone (Ac), acetoacetic acid (AcAc), and β-hydroxybutyric acid (BHB), which is technically not a ketone body but is formed from AcAc. Ketosis has been categorized as type I or type II based on blood glucose and blood insulin.[254] Type I ketosis is the classic primary or spontaneous ketosis, causing a reduction of glucose in the blood and liver (decreased glycogen) and an increased fat mobilization culminating in elevated ketone body accumulations from a negative energy balance during early lactation.[254,255] Type II ketosis involves high blood insulin and transient hyperglycemia secondary to overconditioning and fatty infiltration of the liver (also see Chapter 33 for discussions of fatty liver and pregnancy toxemia). Baird and co-workers[256] stated that "a certain degree of ketosis is a natural state in the ruminant, and the ketotic animal may only represent the extreme of a normal metabolic range." Ketosis becomes a disease condition only when the absorption and production of ketone bodies exceed their use by the ruminant as an energy source, resulting in elevated blood ketones, free fatty acids (FFAs), or nonesterified fatty acids (NEFAs) and decreased blood glucose. The clinical signs of ketosis tend to be vague and nonspecific. Therefore ketosis is classified as clinical or subclinical on the basis of levels of ketone bodies in the blood, urine, and milk and the presence or absence of clinical

signs. Any disease process occurring in early lactation that reduces feed intake may cause secondary ketosis.

41.1.6.1.2

Etiology

Ketosis is a production disease of modern agriculture. Dairy cattle have been genetically selected for high milk yield, which has resulted in elevated milk production during early lactation. This milk production exceeds the capacity of the animal to ingest sufficient feed to meet requirements for energy.[257] The input into the animal must equal or exceed the output to prevent a negative energy balance (Table 41-7).

The milk production of dairy cattle peaks by approximately 4 weeks after parturition, but the dietary intake on a dry matter basis does not peak until 7 to 8 weeks.[258] High-producing dairy cows will be in a negative energy balance for as long as 8 weeks, despite the provision of a high-quality, palatable diet. To offset the negative energy balance, the individual cow must mobilize body fat and protein stores in the form of triglycerides and amino acids for gluconeogenesis. Ketone bodies are normally produced by the liver and ruminal wall, although ruminal wall ketone production is insignificant during clinical ketosis.[259] The mammary gland indirectly contributes to ketone body production by using glucose for lactose production.[260] The liver, however, is the major source of overall ketone production during ketosis. All tissues in the normal cow can adapt to the use of ketone bodies as an alternate energy source except the liver. It must be stressed that normal, high-producing dairy cows will have some level of ketosis during the rising curve of their lactation until their energy intake balances milk production, despite the provision of good-quality feed. During this period cows lose 30 to 100 kg (65 to 220 lb).[261–263] The difficulty is in identifying and preventing the factors that move a cow from the normal level of ketone body formation into the subclinical and clinical categories.

Table 41-7 Summation of Components of Energy Balance in the Bovine

Inputs	Throughputs	Outputs
Food	Digestion	Defecation
Water	Hepatic metabolism	Urination
Respiration and O_2	Fat metabolism	CO_2
Endocrine influences	Mammary gland metabolism	Lactation
Environment and stress		Muscular activity
	Tissue metabolism (fetus)	Heat loss Reproduction

Any disease condition that decreases dietary intake may cause secondary ketosis as a result of increased fat mobilization and ketone production. During the immediate postpartum period cows are susceptible to many diseases that are likely to reduce their normal feed intake. Ketosis may also be secondary to the ingestion of preformed ketones in the diet (silage high in lactic or butyric acid).[258] Biogenic amines such as putrescine, tryptamine, cadaverine, and histamine contained in ketogenic silage may play a role, possibly by decreasing intake.[264,265] Cobalt deficiency has been implicated as a potential cause of ketosis.[266] There is also a high incidence of ketosis in herds affected by fluorosis.[267] Contamination of concentrates with low levels of lincomycin have been reported to cause herd outbreaks of clinical ketosis.

[268] The onset of bovine somatotropin (BST) use in dairies was speculated to increase the incidence of ketosis, but this has not been demonstrated.[269,270]

41.1.6.1.3

Clinical Signs and Differential Diagnoses

Clinical ketosis is most commonly seen as a gradual loss of appetite and decrease in milk production over several days. Loss of appetite is usually sequential, with refusal of grain, then silage, and lastly forages. As feed intake decreases, weight is lost rapidly, and milk production drops. During early lactation, reduction in milk production lags behind the reduction in energy intake. The incidence of type I ketosis tends to occur 3 to 6 weeks postpartum as milk production peaks, in contrast to type II, which is seen immediately after calving.[254] Physical findings include normal vital signs; firm, dry feces; moderate depression; and sometimes reluctance to move. Ruminal motility may be decreased if the animal has been anorectic for several days. Occasionally pica is seen. Often the odor of ketones can be detected on the breath and in the milk. Clinical signs may spontaneously disappear without treatment when an equilibrium between milk yield and dietary intake is reached. Transient nervous signs such as staggering and blindness may occur for short periods of time. Displaced abomasum (particularly left displacement or LDA), metritis, mastitis, and peritonitis (particularly traumatic reticuloperitonitis) are common primary disease entities leading to secondary ketosis. Although LDA has traditionally been thought to result in ketosis, recent work has demonstrated that elevated blood NEFAs and ketones precede LDA by 2 days and increase the risk of the condition by as much as eightfold.[271] Ketosis decreases immunoresponsiveness, leaving affected cows more vulnerable to concurrent infections. This is attributed to the hypoglycemia and suppressive effects of NEFAs.[271] Less common causes of secondary ketosis are subclinical hypocalcemia, mild ruminal overload and laminitis, lameness caused by sole abscesses and ulcers, pyelonephritis, and musculoskeletal injuries after calving.

1364

1365

In the nervous form of ketosis, there is an acute onset of bizarre neurologic signs, including circling, proprioceptive deficits, head pressing, apparent blindness, wandering, excessive grooming behavior, pica, and excessive salivation. These animals may show hyperesthesia, bellowing, moderate tremors, and tetany.[272] They may behave aggressively toward people or inanimate objects and appear ataxic when ambulating. Episodes of nervous signs last 1 to 2 hours and recur at 8- to 10-hour intervals.[260] Diseases such as listeriosis, rabies, lactation tetany, acute lead poisoning, and *Claviceps paspali* poisoning should be considered as possible differential diagnoses.

A very thorough physical examination must be performed to differentiate primary from secondary ketosis. A mild fever and increased heart rate are often associated with primary diseases that are inflammatory in nature. Moderate to severe ketonuria may be seen. During the first 2 weeks after calving, cows may require treatment for concurrent diseases. If appetite does not return after standard therapy for the primary disease entity, further therapy for ketosis may be necessary. The tendency for ketosis to recur necessitates careful reassessment by repeating the physical examination to detect primary diseases causing secondary ketosis.

41.1.6.1.4

Clinical Pathology and Laboratory Aids

Ketone bodies may be detected in urine, plasma, and milk (Table 41-8).[260,273–280] The literature is reported in the International System of Units (SI units) (mmol/L) and conventional units (mg/dL), which makes interpretation difficult. The vagueness of clinical signs has made it difficult to determine precise

definitions of ketone bodies in clinical ketosis. As a general guideline, animals with clinical ketosis will have blood glucose concentrations of 20 to 40 mg/dL, total blood ketones >30 mg/dL, total urine ketones >84 mg/dL, and total milk ketones >10 mg/dL. Individuals with subclinical ketosis are those that have no clinical signs of ketosis but have low-normal blood glucose, total blood ketones of 10 to 30 mg/dL, and total milk ketones of 2 mg/dL. Recent studies have statistically determined BHB to give the best correlation for subclinical ketosis with a threshold of 1400 µmol/L (14.4 mg/dL).[281] Secondary ketosis tends to fall between the ranges for clinical and subclinical ketosis, depending on the duration of the primary disease process.[259]

Table 41-8 Blood, Urine, and Milk Analysis in Ketosis

	Normal		Subclinical		Clinical	
	(mg/dL)	(mmol/L)	(mg/dL)	(mmol/L)	(mg/dL)	(mmol/L)

Commercially available tests have changed substantially in the past few years, with greatly improved diagnostic capability. Urine ketones may give a positive result in otherwise normal cows, because ketones are concentrated to 2 to 20 times the blood ketone level. Ketone bodies in the milk more closely reflect ketone blood levels, making milk ketones a better indicator of ketosis (approximately 50% of blood concentration).[279,280] Of the ketone bodies, AcAc tends to be the most unstable and difficult to detect in samples. Various products that detect the Ac, AcAc, and/or BHB are available. A recent review of available tests found that two products, one detecting AcAc in urine at the “small” reading (Ketostix, Bayer, Elkhart, Ind.) and the other detecting BHB in milk (KetoTest, Sanwa Kagaku Kenkyusho, Nagoya, Japan), had acceptable sensitivity and specificity for screening herds for subclinical ketosis.[282] In a second

study, Pink test liquid (www.profs-products.com, Germany) and Ketolac (Hoescht, Germany) were also found to be satisfactory for diagnosis of subclinical ketosis.[283] Blood levels of volatile fatty acids (VFAs), FFAs, and NEFAs are increased in ketosis. New test kits have been developed that are capable of assessing NEFAs on site (VDx Diagnostic Analyzer, Newburg, Wis.). NEFA levels of >0.5 mEq/L were satisfactory in detecting herd problems with subclinical ketosis.[284,285] Problems exist with diurnal variation in blood levels of VFAs, FFAs, and NEFAs, making timing of blood sampling difficult.[280,286,287] These tests can be used to monitor dairy herds for negative energy balance and the risk of subclinical and clinical ketosis and associated disease problems.[285]

The central role of the liver in energy metabolism of ruminants associates the onset of clinical ketosis with elevations of liver enzymes and abnormal liver function test results. Serum aspartate aminotransferase (AST) and sorbitol dehydrogenase (SDH) may be increased in severe cases. The degree of liver dysfunction is mild compared with that of cows with fatty liver syndrome. The sulfobromophthalein (BSP) clearance test was the classical evaluation of liver function particularly in overconditioned cows at risk for fatty liver syndrome development (see Chapter 33) but is currently unavailable. Serum bile acid levels have had variable results and may not be useful in differentiating mild, moderate, and severe fatty infiltration of the liver, but they do correlate with severe hepatic damage.[288,289] The BSP clearance test also did not differentiate between mild and moderate fatty infiltration of the liver. Liver biopsy and determination of triglyceride or triacylglycerol (TAG) are the gold standards for accurately assessing the degree of hepatic lipidosis and are relatively simple to perform in cattle.[290]

1365

1366

White cell counts vary and may reflect stress or the primary disease process that the animal is experiencing. Studies vary in the reported effect of elevated ketone bodies and decreased blood glucose on lymphocyte proliferation and immunoglobulin production.[271] Serum calcium and magnesium levels may be slightly decreased in animals that are anorectic. Cortisol levels are usually within the normal range, and plasma insulin is elevated initially but depressed as the feed intake is decreased.[254]

41.1.6.1.5

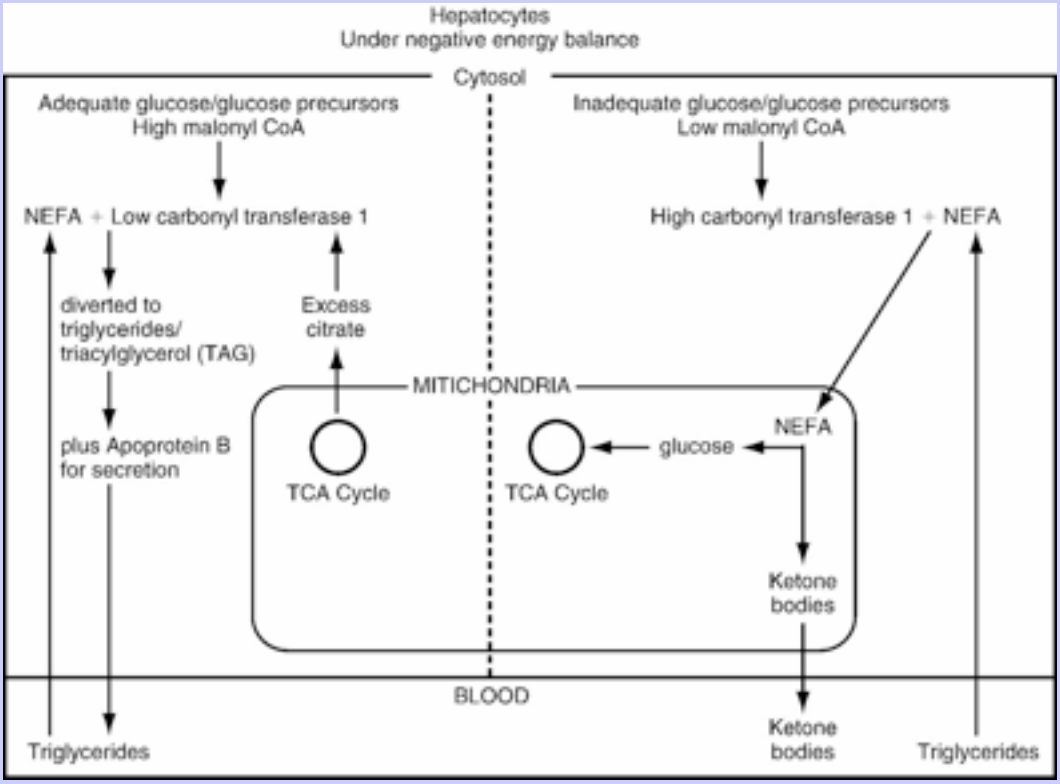
Pathophysiology

Ruminants are exquisitely programmed to use forages in the production of energy for growth, maintenance, pregnancy, and lactation. The control of energy in the ruminant is under the hormonal control of mainly insulin and glucagon. Corticosteroids, GH, catecholamines, and leptins have also been shown to have important roles in the fine-tuning required at the critical times of transition between late pregnancy and early lactation. It is important to keep in mind that ketone bodies are an integral part of normal energy metabolism in ruminants, and it is only when the negative energy balance overwhelms the ability of the cow to use the available ketone bodies that a disease condition occurs.

Control of blood glucose in ruminants is mainly under the control of insulin, which favors cellular uptake of glucose, lipogenesis, and glycogen synthesis while decreasing lipolysis and hepatic gluconeogenesis.[290,291] Ruminants are considered to be relatively insulin resistant, but during early lactation low insulin concentrations are accompanied by high tissue insulin sensitivity.[292] Glucagon counteracts insulin by increasing lipolysis and hepatic gluconeogenesis and decreasing lipogenesis. Catecholamines modulate energy metabolism by favoring lipolysis and decreasing lipogenesis. GH levels are normally high in early lactation and inhibit lipogenesis in adipose while increasing gluconeogenesis in the liver. Adipocytes have been of increasing interest in all species, as they have been shown to produce a variety of endocrine factors (leptin, resistin, IL-6, TNF-α, and adiponectin).[293,294] Leptin has potential for influencing feed intake and

resistance to insulin and increasing energy expenditure and has been documented to be increased in obesity. The extent and importance of these interactions have not been completely investigated in ruminants.

Fig. 41-17 Hepatocyte cellular metabolism under negative energy balance in the presence *(left side)* or absence *(right side)* of adequate glucose or glucose precursors.



In the normal lactating cow, energy is presented to the liver in the form of VFAs, bacterial protein, and a small amount of glucose and protein that escapes degradation in the rumen (Fig. 41-17).[255,260,261] The principal VFAs are acetate, propionate, and butyrate, which are produced in an approximate 70:20:10 ratio, respectively, in the rumen. Acetate is mainly used in fat synthesis, although there is some evidence to suggest that it may be a minor glucose source by entering at the acetyl coenzyme A (CoA) level. Butyrate is condensed into acetoacetyl CoA, which can be partially oxidized to ketone bodies or transformed into acetyl CoA that can enter the tricarboxylic acid (TCA) cycle (no net gain of glucose). Propionate enters the TCA cycle directly at the level of succinyl CoA (equivalent to 30% to 50% of glucose production in the ruminant).[295] Therefore acetate and butyrate are ketogenic, and propionate is glycogenic. The normal ratio of production in the rumen is four ketogenic to one glycogenic VFA. Significant production of ketone bodies occurs in the ruminal epithelium and mammary gland, as well as in the major production site, the liver.[259,295] Ketone bodies are normally used by the TCA cycle in the heart, kidney, skeletal muscles, and mammary gland through the acetyl CoA pathway.

1366
1367

Efficient oxidation of acetyl CoA depends on an adequate supply of oxaloacetate, which is generated from gluconeogenic precursors, mainly propionate (from the rumen) and lactate and pyruvate (from anaerobic metabolism of glucose).[255] Skeletal muscle mass also provides amino acids for gluconeogenesis. Lactating cows preempt a large quantity of propionate and lactate for milk production in the form of lactose.[291] Supplies of oxaloacetate are reduced, slowing down the TCA cycle and the use of acetyl CoA. The backlog of acetyl CoA is diverted into the formation of ketone bodies.

Adipose tissue stores energy in the form of triglycerides, which can be mobilized to provide NEFAs that either enter the TCA cycle through acetyl CoA, adding to the formation of ketone bodies, or are reesterified into triglycerides or TAG (see Fig. 41-17). The ruminant liver is inefficient in partitioning the increased NEFAs into triglycerides and secreting them into the circulation as lipoproteins. Apoprotein B is required to form VLDLs. Deficiency of apoprotein B will result in accumulations of TAG or fatty infiltration of the liver and abnormally elevated ketone bodies. The negative energy balance that occurs in postpartum dairy cows further reduces available carbohydrate and accelerates fat mobilization and ketone body formation. The ketone bodies in clinical ketosis are mainly produced from NEFAs in the liver, which shift in response to low carbohydrate supplies from the pathways of esterification and complete oxidation of acetyl CoA to CO_2 to partial oxidation of acetoacetyl CoA to ketone bodies.[259,291,295] The net results are ketonemia, ketonuria, ketolactia, hypoglycemia, and low levels of hepatic glycogen.

Clinical ketosis in ruminants occurs when the demand for glucose by the mammary gland or fetus exceeds the energy resources available from the diet and fat mobilization, resulting in hypoglycemia. The daily glucose requirements of a dairy cow increase above normal maintenance by 30% in late gestation and by 75% with the onset of lactation.[291] The average energy requirements of a 1000-lb lactating cow have been estimated to be 50 g of glucose per hour.[296] Only 10% of the glucose requirement is available in the form of glucose.

In late pregnancy and early lactation it is common for a negative energy balance to occur, which results in subclinical ketosis. Any additional nutritional, metabolic, or other disorder resulting in decreased feed intake will make the subclinical ketosis clinical.

41.1.6.1.6

Epidemiology

The morbidity of clinical ketosis is extremely variable and difficult to measure. Management and nutrition are influential factors that vary widely from farm to farm and area to area. Prevalence rates (number of cases at a point in time) have been reported to be 13.1% (range 3% to 22%, depending on lactation) for clinical ketosis and 33.8% (range 31% to 41%) for subclinical ketosis.[297,298] Incidence rates (number of cases that occur in 1 year) have been reported to range from 1.87% to 13% for clinical ketosis and 7.3% to 12.1% for subclinical ketosis.[297–301] Studies using newer tests for ketone bodies have reported subclinical ketosis incidence rates of 59% and 43% using cutoff points of 1400 and 1200 μmol/L, respectively.[302] Most cases occur in the first 6 weeks after calving, with the peak incidence at 3 to 4 weeks after calving.[298,303,304] Breed differences have been found, as well as genetic tendencies within bull-daughter families.[299,300] The incidence of clinical ketosis increased with parity, peaking at the fifth to sixth lactation.[298,299] Cows that were diagnosed with clinical ketosis once had increased risk of ketosis at subsequent calvings.[301,303] Recurrence of ketosis in individuals may reflect digestive capacity and metabolic efficiency, as well as milk production, which are likely to have a multifactorial mode of inheritance.

Generally, clinical and subclinical cows are high producers and are overconditioned at calving.[304,305] Fat cows have been shown to have a 25% reduction in dry matter intake (DMI) and higher turnover rates of fatty acids because of more fat mobilization.[306] Environmental factors that affect the incidence of clinical ketosis include season (increased during midwinter), climate, stabling (increased in stabled vs. loose housing), and feeding regimen (increased with number of feedstuffs used and fewer numbers of feedings per day).[301,304,307] Diets that are less than 8% protein on a dry matter basis before calving or that have high protein levels (greater than 20% DM) after calving have been associated with high incidences of herd ketosis.[308] One study reported an association of increased incidence with a high standard of management and decreased incidence if the wife, versus other family members or paid workers, assisted with chores.[307]

Thirty percent to 40% of cases are complicated by concurrent diseases such as metritis, traumatic reticuloperitonitis, and abomasal displacements.[308] These cows are classified as having secondary ketosis. A diagnosis of parturient paresis, alone or in combination with retained placenta, increased the risk of clinical ketosis.[301,304] Cows with metritis are more likely to be diagnosed as having subclinical ketosis.[297] Displaced abomasum and lameness in a previous lactation were associated with clinical ketosis.[304] One study reported that cows with elevated NEFA concentrations prepartum and elevated BHB postpartum had an increased risk of developing an LDA and ketosis.[270] Cystic ovaries, increased calving to first service interval, and increased calving to last service interval have been associated with subclinical ketosis.[297,304,305] Others reported no association between ketosis and the calving interval and number of inseminations.[309] Most genetic studies are based on the lactation previous to the diagnosis of ketosis and have found either no difference or a tendency toward higher production in cows with ketosis.[299,309–312] One study demonstrated a genetic correlation between milk production and ketosis using only first lactation records.[313] Subclinical ketosis was found to be associated with losses of 1 to 1.4 kg of milk per day or 4.4% to 6% of the mean daily production.[297] Other authors[312] found an association between diagnosis and treatment of clinical ketosis, with an increase of 2.5% in production over the entire lactation. A negative correlation of ketosis with culling rate indicated that high-producing cows with ketosis were less likely to be culled than low-producing cows.[301,314]

41.1.6.1.7

Necropsy Findings

The mortality rate from primary ketosis is extremely low. In animals that die with clinical ketosis, a fatty liver is likely to be the only pathologic finding. In secondary ketosis lesions are associated with the primary disease condition.

41.1.6.1.8

Treatment and Prognosis

Treatment of secondary ketosis requires correction of the primary condition while ensuring the provision of an adequate diet. In ketosis secondary to the butyrate content of silage, the diet can be manipulated to eliminate or dilute the silage.[258]

Many treatments have been used for primary clinical ketosis. The goal of treatment is to limit the mobilization of fat by increasing the availability of glucose or glucose precursors and promoting uptake of glucose by cells.[315] The pathophysiologic reasoning for specific treatments of ketosis has been reviewed.

1367
1368

[316] Clinical response to traditional treatment with intravenous glucose, oral propylene glycol, corticosteroids, and insulin has been well documented. In addition, many nontraditional treatments and feed supplements have shown variable success in treating and preventing ketosis.

Traditional therapy with intravenous injections of 100 to 500 mL of 50% glucose (dextrose) gives marked clinical improvement. A transient hyperglycemia is produced; return to preinjection levels occurs in 2 hours. Blood ketones drop immediately, clinical signs disappear, and milk production increases by 5 to l0 lb for at least one milking.[317] Nervous signs may reappear in l2 to 24 hours, and milk production drops again over 2 to 3 days. There are fewer relapses if the glucose injections are repeated frequently. Solutions containing a mixture of 25% dextrose and 25% fructose have been used in an attempt to prolong the hyperglycemic action. Ideally a continuous intravenous glucose infusion at 0.5 g/min should be administered until milk ketone test results are negative.[296,317] In my opinion a slow infusion of 20 L of 2.5% glucose (with half normal saline) over 24 hours improves the clinical response. This solution allows fast enough drip rates for ease of catheter maintenance without the danger of causing osmotic diuresis and excessive water loading. Urine is monitored by dipsticks for negative glucose and decreasing levels of ketone bodies several times daily. Daily monitoring of the blood glucose (once or twice daily) measures the adequacy of dextrose administration. Careful monitoring for hypoglycemia is required when intravenous glucose is discontinued. This may be impractical for field situations but is worthwhile in clinical settings with valuable individuals.

Glucose precursors may be given orally in the feed or as a drench and provide a source for gluconeogenesis. These include a propylene glycol drench at 225 g (8 oz) bid for 2 days, followed by 110 g (4 oz) once daily for 2 days or glycerol at 500 g bid for up to 10 days.[318] Overuse of propylene glycol may have a deleterious effect on ruminal flora, decrease ruminal motility, and cause diarrhea, necessitating its discontinuation and the institution of ruminal transfaunations. In one study, adding propylene glycol to the diet of postpartum cows decreased NEFA and BHB levels but did not significantly change milk production, health, or fertility and therefore was not economically beneficial.[319] Glycerol drenches at 1 to 2 L orally per cow alleviated symptoms of ketosis, but including glycerol in the transition feed did not.[320,321] Sodium propionate (125 to 250 g bid orally), ammonium lactate (120 g bid orally), and sodium lactate (360 g bid orally) have also been used as feed additives to provide alternate glucose sources. All of these tend to lower the butterfat test result and may cause digestive disturbances if prolonged treatment is used.[317]

Glucocorticoids are often used to prolong the hyperglycemic effect by decreasing tissue uptake of glucose and reducing milk production for up to 3 days. Dexamethasone (0.04 mg/kg) and betamethasone are most commonly used. In one study a single treatment of dexamethasone (0.04 mg/kg) significantly increased blood glucose for 6 to 9 days and decreased milk production for 1 to 7 days.[322] Caution must be used, because overdosing may reduce feed intake and exacerbate the condition of cows with fatty liver syndrome.[323] Anabolic steroids such as trienbolone acetate have resulted in decreases in blood levels of ketone bodies without depression of milk production but are prohibited in the United States.[324]

Low doses of long-acting insulin (200 IU of protamine zinc insulin subcutaneously [SC] once every 48 hours) have been used as an adjunct to intravenous glucose and glucocorticoid therapy. Use of the newer slow-release insulin (Humilin, Ultralente human insulin rDNA, Eli Lilly, Indianapolis, Ind.) at a dose of 0.14/IU/kg of body weight IM provided an insulin peak by 12 hours postinjection, with return to preinjection levels by 24 hours.[325] Blood glucose lowered by 21% at 6 to 12 hours and returned to

preinjection levels within 24 hours. Pancreatic secretion of insulin is reduced in ketotic cows in response to intravenous infusions of glucose.[326] Insulin assists in suppressing fatty acid mobilization and increasing tissue uptake of glucose while stimulating hepatic glycolysis. Intravenous glucose combined with insulin when administered over several days has been shown to decrease NEFAs and liver triglycerides and increase hepatic glycogen.[327]

There has been interest in using glucagon injections to stimulate gluconeogenesis and limiting lipolysis, which decreases triglyceride accumulation in the liver during early lactation. Recent studies reported glucagon had no adverse effects but had only minor effects on the lipid transport in early lactation.[328] Glucagon is not commercially available.

Lipotrophic agents such as choline (25 to 50 g daily PO), cysteamine (750 mg IV every 2 to 3 days), and L-methionine have been suggested as feed additives or treatments that increase mobilization of fat in the liver.[329–331] Choline (25 g daily) may also be given subcutaneously but should *not* be given intravenously because it acts as a neuromuscular blocker. Therapy with lipotrophic agents has not been proven effective in controlled trials and may even be harmful in cases of severe liver damage.[330]

Cobalt deficiency and therefore vitamin B_{12} deficiency have been implicated as a cause of ketosis.[263] Vitamin B_{12} is an essential cofactor in the metabolism of propionate as it enters into the TCA cycle.[262] Blood and liver levels of vitamin B_{12} are reduced in the postparturient cow.[266] Although vitamin B_{12} and cobalt may be added to the diet, the effectiveness of vitamin B_{12} has not been proven.[332]

Supplementation of prepartum and early lactation diets with chromium decreased serum NEFAs but had no effect on milk production or milk components.[333] Decreased NEFA was greatest at 1 week postpartum. Chromium may potentiate the action of insulin and has a role in the activation of thyroid hormone.

Nicotinic acid (niacin) and nicotinamide have been used with variable effects.[262] Nicotinamide coenzymes in mammary tissue were reduced in ketotic cows compared with normal cows.[334] The suggested dose of nicotinic acid is 6 g orally once daily for up to 10 weeks after calving. Milk production was slightly increased, and blood levels of ketone bodies and FFAs were lower in niacin-treated cows.[335] Niacin decreases blood ketones and FFAs and increases blood glucose. Niacin has also been used in combination with propylene glycol or monensin, but no significant differences were found between treatment and control groups.[336,337] Biotin is a coenzyme in the process of gluconeogenesis and has been studied in the peripartum period.[338] Although NEFAs and hepatic TAG were lower, biotin did not decrease BHB.

Ionophores increase the ratio of propionate formation in the rumen and have been documented to decrease the incidence of clinical ketosis.[281] As of October 2004 monensin (Rumensin, Elanco, Greenfield, Ind.) was cleared for inclusion in feed for dry and lactating dairy cattle in the United States and is valuable as a tool for preventing clinical and subclinical ketosis.

Chloral hydrate is a traditional treatment that increases the breakdown of starch in the rumen and influences the ruminal production of propionate. The initial oral dose is 30 g, followed by 7 g bid for several days.[317] Chloral hydrate may be particularly helpful for its sedative effects in treating cows with recurring nervous ketosis.

1368
1369

As in all metabolic diseases, nursing care is important. Supportive therapy may include ruminal transfaunations, provision of a variety of palatable feeds, and exercise.

41.1.6.1.9

Prevention and Control

Because the underlying mechanism of clinical and subclinical ketosis is one of negative energy balance during the first 8 weeks of lactation, prevention and control can be addressed in three steps. The feeding and management of cows during late lactation and the dry period should promote good body condition at calving (see Chapter 9 for BCS system). Optimum intake of lactating rations at the commencement of lactation must be encouraged by introducing the ration in a stepwise fashion. The ideal ration during early lactation is highly palatable and of an appropriate energy density.[263,285]

A moderate amount of body fat should be available for mobilization and milk production at parturition. The body fat that is lost in early lactation must be stored in the previous late lactation by feeding to National Research Council (NRC) recommendations.[263] Body condition of the dry cow must be maintained, and fetal growth provided for. It is essential that cows do not become too fat before parturition.[261,305,306] There is evidence that fatty infiltration of the liver begins before parturition, particularly in individuals with fat cow syndrome.[288]

The introduction of the lactating ration should be made as smoothly as possible to encourage maximum intake and minimize digestive upsets. Feeding of the lactation ration in limited amounts may begin as early as 4 to 5 weeks before parturition so that typically 8 to 9 lb of concentrates are being fed at parturition. After calving, incremental increases of a few pounds per day are made until ad lib levels are reached (at approximately 2 to 4 weeks).[260] Ensuring adequate bunk space and minimizing pen changes at the time of parturition will have a critical, positive effect on DMI immediately.[285]

The ideal early lactation ration is highly palatable and meets NRC recommendations. It is beyond the scope of this text to outline detailed ration balancing. The key aspects are maintaining high energy density and optimum levels of fiber and protein without compromising the DMI. Calculations of the energy requirements of a lactating cow are expressed as total net energy of lactation and are obtained from NRC charts.[263] Recommendations for fiber content of the diet are based on the acid detergent fiber (ADF) and NDF. NDF is a good estimate of the bulk of a diet, and the DMI of a ration depends on the NDF (1.2% of body weight). Not all forage analysis laboratories report the NDF, but it can be approximated by dividing the total digestible nutrients by 100. Protein should be provided as both rumen degradable (soluble and nonprotein nitrogen) and rumen undegradable (bypass). Excess protein and fat should be avoided.[285] Specific instructions for formulating these ingredients into a ration are provided by multiple ration-balancing programs.[263]

The diet must also be balanced in its minerals. Cobalt may be added if there is an indication of inadequate levels. Nicotinic acid is recommended as a feed additive at 6 to 12 g/head/day in early lactation rations.[335] Inclusion of chromium in peripartum diets may also be beneficial.[333]

Problems that arise from silage with high butyrate concentrations may require substitution or dilution of the affected silage with other feeds for the cows in early lactation. High-butyrate diets are often tolerated because they encourage a higher milk butterfat content.[258,317] The addition of protected fats in the form of

the calcium salts of long-chain fatty acids or a high proportion of saturated long-chain fatty acids (palmitic and stearic acids) increases the energy density of the ration without reducing the fiber content.[339] These compounds are not degraded in the rumen but are digested in the abomasum and small intestine. Feeding protected fats results in increased milk production, slightly decreased DMI, and increased FFAs, as well as stabilized blood ketones and weight loss through a glucose-sparing effect. However, there is some evidence that added fat does not help in the periparturient period and may interfere with other treatments.[340] Glucogenic precursors such as propylene glycol and sodium propionate have been incorporated into early lactation rations for many years. Both of these compounds are not palatable to dairy cattle and are better reserved for treatment of individual cases of ketosis.

Subclinical and clinical ketosis should be detected and treated as early as possible to prevent deleterious effects on health and production. This may be accomplished by encouraging clients to use ketone tests routinely on milk or urine during the first 50 to 60 days after parturition. Several companies are developing commercial automated sampling systems that can routinely test milk for ketone bodies.[341–343] Cattle with positive test results should have a thorough physical examination. Institution of supportive therapy for subclinical ketosis should include administration of oral propylene glycol. A high prevalence rate of clinical and/or subclinical ketosis would necessitate investigation of the feeding program.

41.1.7 CALCIUM, MAGNESIUM, AND PHOSPHORUS

JESSE P. GOFF

Adequate blood calcium (Ca), magnesium (Mg), and phosphorus (P) concentrations are vital to normal function of animals. Mechanisms for maintaining blood Ca, Mg, and P concentrations within normal limits perform efficiently most of the time. Occasionally, these homeostatic mechanisms fail, and metabolic diseases, such as milk fever, occur. Inadequate blood Ca, P, Mg, or potassium (K) concentrations (discussed later in chapter) can cause a cow to lose the ability to rise to her feet, as these minerals are necessary for nerve and muscle function. Less severe disturbances in blood concentrations of these minerals can cause reduced feed intake, poor ruminal and intestine motility, poor productivity, and increased susceptibility to other metabolic and infectious disease.

41.1.7.1 CALCIUM

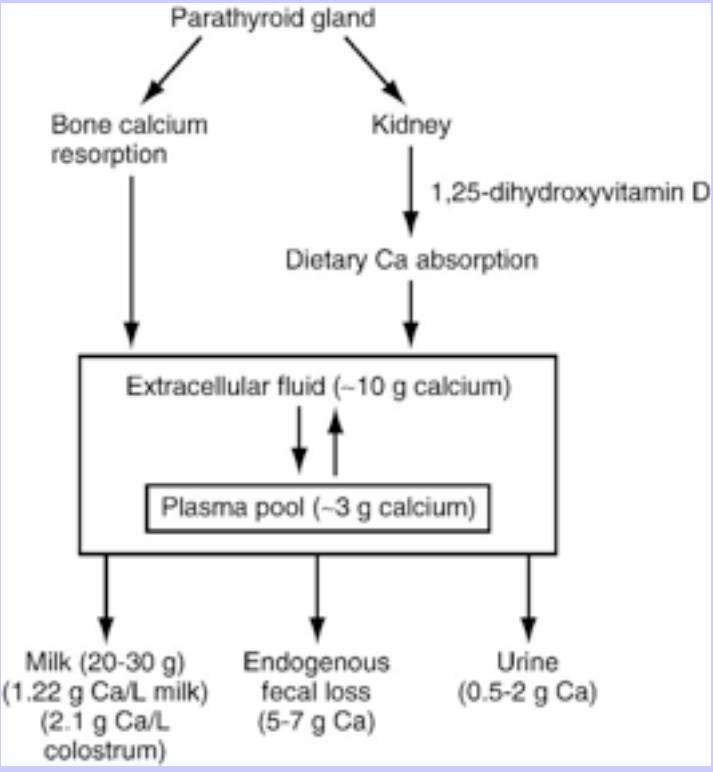
Ca is the major mineral of bone. The skeleton of a 600-kg cow contains approximately 8.5 kg of Ca. Extracellular Ca is also essential to ensure transmission of nervous tissue impulses, excitation of skeletal and cardiac muscle contraction, and blood clotting and as a component of milk. Intracellular Ca, although 1/10,000 the concentration of extracellular Ca, is involved in the activity of a wide array of enzymes and serves as an important second messenger conveying information from the surface of the cell to the interior of the cell. Low extracellular Ca concentration causes hyperexcitability of the nervous system, causing muscle fasciculations or even tetany. At the neuromuscular junction, the amount of acetylcholine released during an endplate action potential is directly related to the amount of Ca that enters the terminal end of the motor neuron, which is in turn dependent on extracellular Ca concentration. Thus, hypocalcemia reduces the strength of muscle contraction, resulting in paresis. In many species (dog, cat, human, horse) the prevailing effects of hypocalcemia result in tetany. In the cow and sheep, hypocalcemia manifests as paresis, though it is important to point out that both effects of hypocalcemia are occurring at the same time and careful evaluation of a hypocalcemic animal will reveal both signs.

41.1.7.1.1

Calcium Homeostasis

Blood Ca concentration in the adult cow or sheep is maintained at 8.5 to 10 mg/dL and is slightly higher in young animals (Fig. 41-18). There are approximately 3 g of Ca in the plasma pool of a 600-kg cow and 8 to 9 g in the extracellular pool. The Ca concentration in the blood is tightly regulated, primarily by the parathyroid gland, which responds to even a small decrease in Ca concentration by secreting PTH into the blood. PTH first will act on the kidney to increase renal tubular reabsorption of Ca from the glomerular filtrate. However, because only small amounts of Ca are lost in urine (<1 to 2 g/day in the cow), this action of PTH is sufficient to restore normal blood Ca concentration only if the total deficit is small. Larger Ca deficits cause prolonged secretion of PTH (hours to days), which stimulates osteoclastic resorption of bone Ca and stimulates renal production of 1,25-dihydroxyvitamin D. The 1,25-dihydroxyvitamin D stimulates the intestinal epithelial cells to produce Ca binding proteins and Ca pumps so that Ca within the lumen of the gut is efficiently transported across the intestinal epithelial cells into the blood. Should an animal be fed a Ca- or vitamin D—deficient diet, it will generally maintain normal blood Ca concentrations for weeks to months by resorbing bone Ca. However, this ultimately will cause bone disease such as osteoporosis and osteomalacia. An increase in blood Ca concentration above normal shuts off PTH and stimulates release of calcitonin from the thyroid gland C cells. This hormone increases renal clearance of Ca and decreases osteoclast activity so more Ca is retained in bone.

Fig. 41-18 Calcium (Ca) homeostatic response of the 600-kg cow in early lactation to a decline in blood calcium concentration at the onset of lactation.



41.1.7.2

ACUTE HYPOCALCEMIA (MILK FEVER) IN DAIRY COWS

Nearly half of all dairy cows will experience subclinical hypocalcemia (<7.5 mg/dL) within 24 hours of calving. Although this reduces ruminal and abomasal contractility and reduces feed intake, clinically these animals appear normal. Hypocalcemia also contributes to metritis, mastitis, and retained placenta by negatively affecting uterine and teat sphincter contractility and the immunity of the cow. With further reduction in blood Ca concentration the animals can appear ataxic, and some will be slightly bloated as eructation is reduced. Finally, in as many as 5% of U.S. cows, blood Ca will fall below 5 mg/dL, and in a few Ca will be as low as 2 mg/dL. These cows are recumbent and unable to rise and have a condition commonly referred to as *milk fever* or *parturient paresis*. They often lay with the neck out in an S-shaped curve, and close examination of muscles in the legs and neck will reveal fasciculation of some muscle groups. The heart muscle does not contract strongly, so on auscultation the heartbeat is muffled. The heart rate is generally increased to try to compensate for the low ventricular ejection volumes. The cow loses the ability to thermoregulate and takes on the ambient temperature of its surroundings. In most cases this causes the skin, especially skin of the ears, to be cold. However, in hot climates or when the cow is recumbent in the hot sun the body temperature may be elevated well above normal. Milk fever typically occurs within a day or two of calving—usually after but occasionally just before calving.

Acute hypocalcemia also occurs with many infectious conditions, such as mastitis or metritis, especially if endotoxins are elaborated. As a rule the blood Ca concentration is 6 to 8 mg/dL. This form of hypocalcemia is a result of redistribution of Ca within organs and will not be discussed further other than to note that not all hypocalcemic cows have the syndrome known as milk fever (Box 41-4).

Treatment of milk fever and hypocalcemia should be done as early as possible, especially if recumbency is present. The pressure exerted by the massive weight of the cow can cause a “crush syndrome” effect on the down side appendages in as little as 4 hours. This causes ischemia of the muscles and nerves and is followed by necrosis of these tissues, resulting in the “downer syndrome” cow.[344] The fastest way to restore normal plasma Ca concentration is to administer an intravenous injection of Ca salts (commonly Ca borogluconate). In general, commercial preparations for intravenous use supply from 8.5 to 11.5 g of Ca per 500 mL. They may also contain sources of Mg, P (often as ineffective phosphite), and glucose. The most effective intravenous Ca dose is approximately 2 g of Ca per 100 kg of body weight. A good rule of thumb is to administer the Ca at a rate of 1 g/min. If Ca is administered too rapidly, fatal arrhythmia of the heart and cessation during systole can occur. Intravenous Ca treatments increase blood Ca above normal for approximately 4 hours. Ca salts can also be injected subcutaneously, but absorption is variable because blood flow to the periphery is often compromised. The amount of Ca that can be injected into a single subcutaneous site should be limited to 1 to 1.5 g of Ca (50 to 75 mL of most commercial preparations). Ca preparations designed for intramuscular administration are also available (Ca levulinate or Ca lactate). Most of these preparations must be limited to 0.5 to 1 g of Ca per injection site to avoid tissue necrosis. To get an effective dose of Ca into the clinically hypocalcemic animal might therefore require 6 to 10 injections into widely separated spots. Oral Ca treatments are not recommended as treatments for clinical milk fever cases, although they can be effective aids in prevention of milk fever.

41.1.7.2.1

Box 41-4 Primary Causes of Recumbency Initiating the?"Downer Cow Syndrome"

Mineral imbalances

- Hypocalcemia—plasma Ca <5 mg/dL
- Hypomagnesemia—plasma Mg <1.2 mg/dL
- Hypophosphatemia—plasma P <1.5 mg/dL

Severe toxemia—moderate reduction in plasma Ca, Mg, and P

Dystocia

Pregnancy toxemia syndrome—low plasma Ca, Mg, P, and glucose

Fractures

Coxofemoral luxation

Rupture of gastrocnemius muscle

Lymphosarcoma of spinal cord

41.1.7.3

HYPOCALCEMIA IN LATE-GESTATION BEEF COWS AND EWES

For beef cows and ewes, especially those carrying twins, meeting the sudden increase in fetal skeletal demand (8 to 10 g/fetal calf/day) for Ca often presents a greater challenge to Ca homeostasis than does lactation. Estrogen, which increases dramatically in late gestation, decreases osteoclast activity. This reduces the ability to use bone Ca reabsorption to meet fetal skeletal Ca demands. As a result, most primary hypocalcemic disorders of the beef cow and ewe occur in late gestation. They are usually prevented by increasing Ca and/or Mg in the gestation diet; provided the animal is eating. Often the syndrome in beef cows and ewes is complicated by inadequate energy intake and a state of inappetence associated with the pregnancy toxemia syndrome.

41.1.7.3.1

Etiology of Milk Fever

Dairy cows producing colostrum (containing 1.7 to 2.3 g of Ca per kilogram) or milk (containing 1.2 g of Ca per kilogram) typically secrete 20 to 30 g of Ca each day in early lactation. Put simply, hypocalcemia and milk fever occur when cattle do not obtain enough Ca from their bones and diet to replace Ca lost to milk. The long-accepted reason this occurs was that high dietary Ca fed to the cow before calving placed

the cow in such a state of positive Ca balance that the parathyroid gland atrophied, rendering it too sluggish to adequately respond when onset of lactation placed the cow into negative Ca balance. However, in recent years it has been discovered that high dietary Ca does not have this effect, and in most cases PTH secretion is quite adequate in these animals.

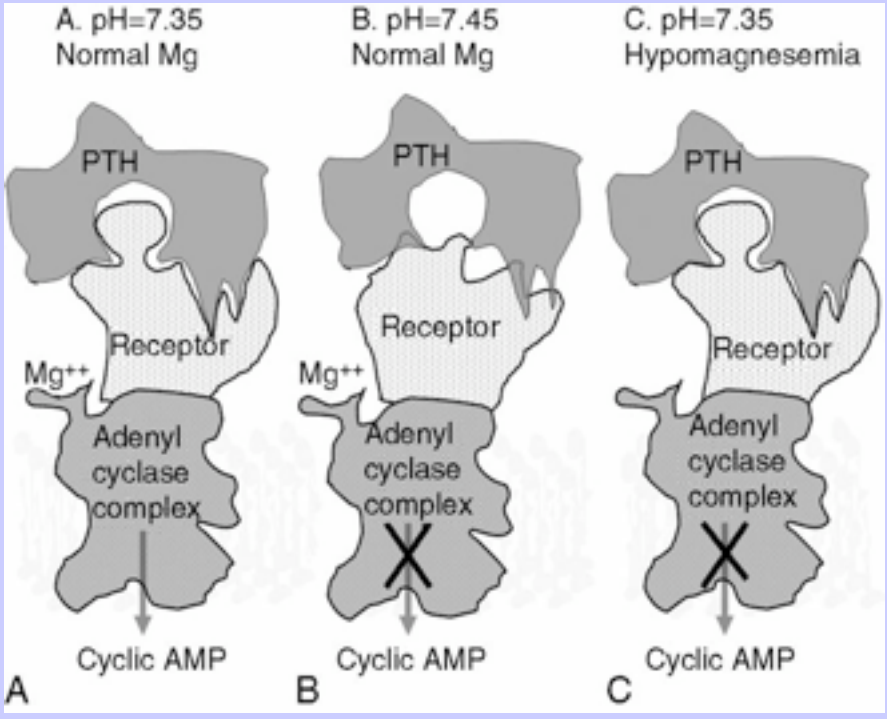
41.1.7.3.2

Role of Metabolic Alkalosis

Metabolic alkalosis predisposes cows to milk fever and subclinical hypocalcemia by altering the conformation of the PTH receptor, rendering the tissues less sensitive to PTH (Fig. 41-19).[345–347] Lack of PTH responsiveness by bone tissue prevents effective use of bone canaliculi fluid Ca (sometimes referred to as *osteocytic osteolysis*) and prevents activation of osteoclastic bone resorption. Failure of the kidneys to respond to PTH reduces renal reabsorption of Ca from the glomerular filtrate. More important, the kidneys fail to convert 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. Therefore enhanced intestinal absorption of dietary Ca, which normally would help restore blood Ca to normal, fails to be instituted.

Metabolic alkalosis of dairy cows is caused by high-potassium diets. This is best explained by Stewart's[348] strong ion difference theory of acid-base physiology, which states that the number of moles of positively charged particles (cations) in any given solution (including body fluids) must equal the number of moles of negatively charged particles (anions) in the solution. Put into extremely simplified terms, if positively charged particles are added to a solution, such as the plasma, the number of H^+ cations will decrease and the number of OH^- anions will increase to maintain the electroneutrality of the solution (the solution becomes more alkaline). Conversely, adding anions to a solution causes an increase in H^+ and a decline in OH^- to maintain electroneutrality, and the pH decreases (the solution becomes more acidic).

Fig. 41-19 Parathyroid hormone (PTH) effects at the surface of target bone and kidney cells. **A,** Under normal conditions, PTH released in response to hypocalcemia interacts with its receptor, located on the surface of bone and kidney cells, in a lock-and-key fashion. This stimulates G-proteins and adenylate cyclase (adenylate cyclase complex), resulting in production of cyclic adenosine monophosphate (AMP), which acts as a second messenger within the cytosol of target cells. This initiates mechanisms such as bone calcium (Ca) reabsorption and renal production of 1,25-dihydroxyvitamin D to restore blood Ca concentration to normal levels. **B,** Alkalotic conditions induced by high-potassium diets induce a change in the shape of the PTH receptor protein so that it is less able to recognize and bind PTH, resulting in failure to activate the cell by producing cyclic AMP. **C,** Magnesium is required for function of the adenylate cyclase complex. Hypomagnesemia reduces the ability of PTH-stimulated cells to produce cyclic AMP, resulting in failure to activate the cell.



Cations and anions enter the blood from the digestive tract, making the cation-anion difference of the diet the ultimate determinant of blood pH. The major cations present in feeds and the charges they carry are sodium (+1), potassium (+1), Ca (+2), and Mg (+2). The major anions and their charges found in feeds are chloride (−1), sulfate (−2), and phosphate (assumed to be −3). Cations or anions present in the diet will alter the pH of the blood only if they are absorbed into the blood. The difference between the number of cation and anion particles absorbed from the diet determines the pH of the blood.

When formulating dairy cow late-gestation diets, the cation-anion difference of a diet is described in terms of mEq/kg or mEq/100 g of diet, using various equations involving Na, K, Ca, Mg, Cl, sulfur, and P, with and without adjustments for absorbability of each mineral in the diet:

$$\text{Dietary Caution - Anion Difference (DCAD)}$$
$$= (Na^{+} + K^{+}) - (Cl^{-} + S^{--})$$
$$= (Na^{+} + K^{+}) - (Cl^{-} + 0.6S^{--})$$
$$= (0.2Ca^{++} + 0.16Mg^{++} + Na^{+} + K^{+}) - (Cl^{-} + 0.6S^{--} + 0.64P^{---})$$

The equations largely become an academic pursuit, as several of the variables in the formulas shown are somewhat fixed constants. A strategy I use is to set dietary Ca at 0.85% to 1% and dietary P and Mg at 0.4%. Dietary sulfur needs to be above 0.22% to ensure adequate substrate for ruminal microbial amino acid synthesis but below 0.4% to avoid possible neurologic problems associated with sulfur toxicity. The key to milk fever prevention is to keep sodium and potassium as close to the requirement of the cow as possible (0.1% for Na and 1% for potassium). The key to reduction of subclinical hypocalcemia is to then add chloride to the ration to counteract the effects of low levels of potassium on blood alkalinity. As a rule of thumb, the amount of dietary chloride needed to acidify the cow's blood (and urine) is approximately 0.5% less than the concentration of K in the diet. For example, if dietary K can be reduced to only 2% of the diet, Cl would need to be roughly 1.5% to acidify the cow. This level of Cl in the diet is likely to cause a decrease in DMI. Chloride sources differ in their palatability, and because achieving low dietary K can be difficult, it is prudent to use a palatable source of Cl when formulating the diet. Ammonium chloride (or ammonium sulfate) can be particularly unpalatable when included in rations with a high pH. At the higher pH the ammonium cation is converted to ammonia, which is highly irritating when smelled by the cow. Prilling the Cl (and SO_4) salts can reduce the unpleasant taste of the salts. In our experience, hydrochloric acid has proved the most palatable source of anions. Hydrochloric acid can be extremely dangerous to handle when it is procured as a liquid concentrate. Several companies now manufacture hydrochloric acid —based anion supplements that are safe to handle.

1371
1372

These are simply guidelines for anion supplementation that I use and are based on inclusion of Ca, Na, S, Mg, and P at the levels outlined previously. Urine pH of the cows provides a cheap and relatively accurate assessment of blood pH and can be a good gauge of the appropriate level of anion supplementation.[349] Urine pH on high-cation diets is generally above 8.2. Limiting dietary cations will reduce urine pH only a small amount (pH 7.5 to 7.8). For optimal control of subclinical hypocalcemia the average pH of the urine of Holstein cows should be between 6.2 and 6.8, which essentially requires addition of anions to the ration. In Jersey cows the average urine pH of the close-up cows has to be reduced to between 5.8 and 6.3 for effective control of hypocalcemia. If the average urine pH is between 5.0 and 5.5, excessive anions have

induced an uncompensated metabolic acidosis, and the cows will experience a decline in DMI. Urine pH can be checked 48 or more hours after a ration change. Urine samples should be free of feces and made on midstream collections to avoid alkalinity from vaginal secretions. Anion-supplemented diets are generally fed for the last 2 to 3 weeks before calving.

41.1.7.3.3

High Dietary Phosphorus

High blood P concentrations inhibit the activity of the renal 25-hydroxyvitamin D 1α-hydroxylase enzyme.[350–351] As summarized by Jorgensen,[352] the incidence of milk fever increases when dietary P exceeds 90 g/day and little negative effect of dietary P is seen when dietary P is less than 50 g/day. Cows need approximately 35 to 40 g of P each day.[353]

41.1.7.3.4

Use of Low-Calcium Prepartal Diets to Prevent Milk Fever

By feeding late-gestation cows a diet that supplies less Ca than they require, the cows can be placed into negative Ca balance. This causes a minor decline in blood Ca concentration, which stimulates PTH secretion, which in turn stimulates osteoclastic bone resorption and renal production of 1,25-dihydroxyvitamin D. This increases bone Ca release and prepares the intestine to absorb Ca efficiently, should it become available. At parturition, the lactational drain of Ca is more easily replaced because the cow's bone osteoclasts are already active and in high numbers and the previous stimulation of enterocytes by 1,25-dihydroxyvitamin D allows efficient use of dietary Ca. Unfortunately, a truly low-Ca diet should supply considerably less than 20 g of absorbed Ca per day. This is difficult to actually achieve on most dairy farms, although increasing use of straw in prepartal diets and the use of Ca binders, such as zeolite or vegetable oils, may make this approach more practical.[354]

41.1.7.3.5

Physiologic Milk Fever Risk Factors

The incidence of milk fever rises as a cow ages, especially as she enters her third or greater lactation. As animals age the number of active bone cells is reduced. Heifers, which are still growing, rarely have problems with hypocalcemia. Lower numbers of active osteoblasts mean fewer cells to respond to PTH and mobilize bone Ca. In addition, as animals age the number of receptors for 1,25-dihydroxyvitamin D on target tissues declines.

The incidence of milk fever is higher in Jersey cows compared with Holstein cows. Although Jersey cow colostrum and milk Ca concentration tend to be higher than in Holsteins, this does not appear to be the only factor. Preliminary data from our laboratory suggest that the intestine of Jersey cows possesses approximately 15% fewer receptors for 1,25-dihydroxyvitamin D than does intestine of Holstein cows.

41.1.7.3.6

Preventing Milk Fever with Vitamin D

Earlier literature often recommended feeding or injecting massive doses (up to 10 million units) of vitamin D 10 to 14 days before calving to prevent milk fever. This will pharmacologically increase intestinal Ca absorption and can help prevent milk fever. Unfortunately, the dose of vitamin D that effectively prevents milk fever is very close to the level that causes irreversible metastatic calcification of soft tissues, and therefore this strategy cannot be recommended. Lower doses may actually induce milk fever because the

high levels of 25(OH)D and 1,25-dihydroxyvitamin D induced by the treatment suppress PTH secretion and directly suppress renal synthesis of endogenous 1,25-dihydroxyvitamin D.[355]

Treatment with 1,25-dihydroxyvitamin D and its analogues can be much more effective, but problems with timing of administration, withdrawal from treatment, expense, and availability have made these treatments not practical.[356,357]

41.1.7.3.7

Hypomagnesemia as a Cause of Hypocalcemia

Hypomagnesemia affects Ca metabolism in two ways. Moderate hypomagnesemia (<1.6 mg/dL) interferes with PTH action on tissues. When PTH binds its receptor on bone or kidney tissues, it normally initiates activation of adenylate cyclase and phospholipase C, resulting in production of the second messengers, cyclic adenosine monophosphate (AMP) and inositol 1,4,5-triphosphate. Both adenylate cyclase and phospholipase C have an Mg^{++} binding site that must be occupied by an Mg ion for full activity.[358] Hypomagnesemia, from inadequate absorption of dietary Mg, is the second most common cause of milk fever in cows around the time of calving and is the most common cause of midlactation milk fever in dairy cows. More severe hypomagnesemia (<1.2 mg/dL) can inhibit PTH secretion in response to hypocalcemia. 1372
This appears to be a factor in the development of some hypomagnesemic tetany syndromes of grazing beef 1373
and dairy cattle. In these syndromes blood Mg concentration falls slowly over time until such point that PTH function is impaired. It is at this point that blood Ca concentration declines precipitously and clinical symptoms, such as tetany, become apparent.[359]

41.1.7.3.8

Agronomic Considerations for Producing Low—Dietary Cation-Anion Difference Forages

Reducing K in the ration of the late-gestation cow can present a problem. By restricting K application to the soil, it is possible to avoid luxury consumption of K by legumes and cool season grasses. Producers should also be aware that forages take up Cl from the soil, and it is possible to find hays that are low in K and high (1% to 1.2%) in Cl. Producers should use the lowest DCAD forage possible, not simply the lowest K forage. Forages intended for the close-up dry cow should routinely be analyzed for both K and Cl by a wet chemistry method. Near infrared determinations of forage mineral content are not currently useful.

41.1.7.3.9

Oral Calcium Treatments at Calving

Ca is absorbed across the intestinal mucosa by two methods. The first method is by the active transport of Ca across intestinal cells—a process mediated by the hormone 1,25-dihydroxyvitamin D. The second method is by passive diffusion across the tight junctions that hold adjacent mucosal cells together. The concept behind oral Ca supplementation is that the cow's ability to use active transport of Ca *across* intestinal cells is inadequate to help her maintain normal blood Ca concentrations. By giving the animal large amounts of very soluble Ca, it is possible to force Ca across the intestinal tract by means of passive diffusion *between* intestinal epithelial cells. Best results are obtained with doses of Ca between 50 and 125 g. For best control of hypocalcemia, a dose is given at calving and again 24 hours later. Administering 50 g of Ca from CaCl as a drench in 250 mL of water is roughly equivalent to administering 4 g of Ca intravenously.[360] Unfortunately, hypocalcemic cows have poor swallowing and gag reflexes, making them vulnerable to aspiration pneumonia. Aspiration of Ca solutions leads to a severe pneumonia. Ca chloride

has been used in oral Ca preparations but can be very caustic. Ca propionate is less injurious to tissues and has the added benefit of supplying propionate, a gluconeogenic precursor. Toxic doses of Ca can be delivered orally; approximately 250 g of Ca in a soluble form will kill some cows.

41.1.7.4 CHRONIC CALCIUM DEFICIENCIES

41.1.7.4.1 Nutritional Secondary Hyperparathyroidism

A deficiency of dietary Ca or vitamin D can reduce the amount of Ca that can be absorbed across the intestine into the extracellular fluids. Diets severely deficient in Ca will not supply adequate Ca to replenish Ca lost from extracellular pools. As a result, blood Ca concentration decreases and PTH secretion increases. PTH can act on the kidney to reduce urinary Ca loss and increase synthesis of 1,25-dihydroxyvitamin D to enhance intestinal Ca absorption efficiency. But if dietary Ca is very low, increasing the efficiency of intestinal Ca absorption cannot substantially increase the amount of Ca entering the extracellular pool of Ca. The only action of PTH that can improve blood Ca concentration in this situation is to enhance bone Ca resorption. The continued removal of bone without replacement results in fibrous osteodystrophy. The clinical signs of nutritional secondary hyperparathyroidism include hypertrophy of the parathyroid glands (although they rarely can be palpated) and cessation of growth in young animals. The lack of Ca available for mineralization of bone matrix causes the growth plates to be soft, weak, and swollen. The cortices of the long bones are thin, and minor or major fractures are common.

Vitamin D deficiency prevents the kidneys from being able to synthesize 1,25-dihydroxyvitamin D. Therefore unless dietary Ca is greatly elevated, the reduced efficiency of dietary Ca absorption will prevent adequate Ca from entering the extracellular fluids, and, again, PTH will activate bone resorption mechanisms to attempt to maintain normocalcemia.

41.1.7.4.2 Renal Secondary Hyperparathyroidism

Renal secondary hyperparathyroidism is a syndrome caused by renal failure and is occasionally observed in older animals. In cows, pyelonephritis can develop in late gestation through early lactation owing to poor urine flow and retrograde urine flow resulting in destruction of renal tissue. A major function of the kidneys in most species is to remove excess phosphate from the circulation. As renal function is lost, phosphate is retained and hyperphosphatemia develops. This occurs when the remaining amount of functional renal tissue is less than 25% of normal.

Hyperphosphatemia has two effects. The first effect is to reduce the ionized Ca content of the blood. This is because Ca and phosphate ions normally exist in blood at concentrations that are slightly below the levels that would cause saturation of the fluids resulting in precipitation of Ca phosphate salt from the solution. However the greatly elevated phosphate level in the blood of renal failure patients can exceed the equilibrium of Ca and phosphate in solution, causing precipitation of Ca from the blood. More important, as phosphate builds up in the blood it has a second effect on the remaining renal tissue. It blocks the activation of the 1α-hydroxylase that catalyzes conversion of 25-dyhydroxyvitamin D to 1,25-dyhydroxyvitamin D within the kidney. Therefore even though PTH should stimulate the remaining functional renal tissue to produce 1,25-dyhydroxyvitamin D, this action of PTH is blocked by hyperphosphatemia.

As renal function is lost, the amount of renal tissue available for production of 1,25-dyhydroxyvitamin D decreases, and blood concentrations of 1,25-dyhydroxyvitamin D decline. This reduces dietary Ca absorption and further depresses blood Ca concentration. This in turn stimulates increased PTH secretion, and reabsorbing bone Ca reserves again becomes a major means of maintaining normocalcemia. Fibrous osteodystrophy follows the prolonged secretion of PTH.

As bone Ca is reabsorbed, more P is also reabsorbed. However, the loss of renal function prevents PTH from having its usual phosphaturic effect, exacerbating the hyperphosphatemia. A vicious cycle of increasing blood P, increasing PTH, and increased bone resorption ensues. The loss of renal function can rarely be reversed.

41.1.7.4.3

Osteoporosis

Three forms of osteoporosis commonly occur. Of these, only lactational osteoporosis is a common syndrome of concern in animals. During lactation in virtually all species there is an obligatory loss of bone mass from the skeleton. In this case the osteoclasts within a bone resorption unit reabsorb bone to a 50-micron depth if dietary Ca is adequate, or to greater depths if the animal is in severe negative Ca balance. 1373 1374 However, osteoblast movement into the resorption cavity is transiently inhibited, and no new bone is deposited. This occurs to some extent in all females shortly after parturition, even when they are in positive Ca balance. However, the degree and duration can be magnified greatly by negative Ca balance. Once the animal has undergone the obligatory period of lactational osteoporotic bone loss (4 to 5 weeks in the cow), if the animal is in positive Ca balance the osteoblasts migrate to the resorption cavity and replace the lost bone. Lactational osteoporosis can help the female meet the Ca demands of lactation by uncoupling bone formation from bone resorption. In high-producing dairy cows, dietary Ca intake is inadequate to meet lactational Ca demands for the first 4 to 6 weeks of lactation. These animals can lose as much as 13% of their skeletal mass during this period, which is replaced in later lactation when dietary Ca intake allows the cow to enter a period of positive Ca balance.

41.1.7.5

MAGNESIUM

Mg is a major intracellular cation serving as a cofactor for enzymatic reactions vital to every major metabolic pathway. Extracellular Mg is vital to normal nerve conduction, muscle function, and bone mineral formation. In a 600-kg cow there is approximately 0.84 g of Mg in the blood, 3 g of Mg in the extracellular fluids, 84 g of Mg inside cells, and 210 g of Mg within bone mineral. Bone is not a significant source of Mg that can be used in times of Mg deficit, as bone reabsorption occurs in response to Ca homeostasis, not Mg status. Maintenance of normal plasma Mg concentration is nearly totally dependent on continuous dietary Mg absorption.

41.1.7.5.1

Hypomagnesemia

Hypomagnesemia generally leads to hyperexcitability, tetany, convulsion, and, too often, sudden death. Hypomagnesemia is often accompanied by and complicated by hypocalcemia. Hypomagnesemia is a common problem in ruminants.

Normal plasma Mg concentration is 1.8 to 2.4 mg/dL in cows and 2.2 to 2.8 mg/dL in sheep. The kidneys play a key role in maintaining Mg homeostasis under conditions of hypermagnesemia when they fail to reabsorb Mg from glomerular filtrate, increasing renal Mg excretion to lower blood Mg concentration. The

renal threshold for Mg (plasma concentration at which all Mg filtered across the glomerulus is reabsorbed) is 1.8 mg/dL in the cow and 2.2 mg/dL in sheep. Plasma Mg concentrations below these levels indicate that dietary Mg absorption is not sufficient and little or no Mg will be detected in urine.

Moderate hypomagnesemia (1.1 to 1.8 mg/dL) is associated with reduced feed intake, nervousness, and reduced milk fat and total milk production. This can be a chronic problem in some dairy herds that often goes unnoticed. It can also predispose these animals to milk fever as described earlier.

41.1.7.5.2

Role of the Rumen in Hypomagnesemia

Mg is well absorbed from the small intestine of young calves and lambs. As the rumen and reticulum develop, these sites become the main, and perhaps the only, sites for net Mg absorption.[361] In adult ruminants the small intestine is a site of net secretion of Mg. Mg absorption from the rumen is dependent on the concentration of Mg in solution in the ruminal fluid and the integrity of the Mg transport mechanism, which is an Na-linked active transport process.[362]

The soluble concentration of Mg in ruminal fluid can be low for several reasons. Chief among these are low Mg content of forages and inadequate dietary supplementation. Mg solubility also declines sharply as ruminal pH rises above 6.5. Grazing animals tend to have higher ruminal pH because of the stimulation of salivary buffer secretion. When high-grain rations are fed, ruminal fluid pH is often below pH 6.5, increasing Mg solubility and thus availability. Forages can also contain organic compounds, such as unsaturated fatty acids, which are converted to tricarballylate, which can form insoluble Mg salts in the rumen.

High dietary K can reduce the rumen's ability to absorb Mg. High K concentration in the ruminal fluid depolarizes the apical membrane of the ruminal epithelium, reducing the electromotive potential needed to drive Mg across the ruminal wall.[362] Feeding ionophores (monensin, lasalocid) can improve activity of the Na-linked Mg transport system in the rumen, increasing Mg absorption efficiency approximately 10%.[363] Lush high-moisture pastures increase the rate of passage of material, including Mg, from the rumen so that Mg may leave the rumen before it can be absorbed.

41.1.7.5.3

Occurrence of Hypomagnesemic Tetany

Hypomagnesemic tetany occurs most often in beef cows, dairy cows, and ewes in early lactation grazing lush pastures high in potassium and nitrogen and low in Mg and Na. This is often referred to as *grass tetany, spring tetany, grass staggers,* or *lactation tetany*. Mg deficiency occurs most often in spring or fall when pastures are growing at maximal rates and is most common in grazing lactating ruminants, as milk production removes 0.15 g of Mg from the blood for each liter of milk produced. Cool weather seems to play a factor as well, probably through its effects on plant Mg uptake, although there is some indication that the physiologic response of the cow to cool weather affects Mg status directly.

When plasma Mg levels fall below 1.1 mg/dL, twitching is sometimes seen in the muscles of the face, shoulder, and flank. As hypomagnesemia progresses, tetanic spasms of the muscles become more common, eventually causing the cow or ewe to stagger and fall. Clonic convulsions quickly follow, with chomping of the jaws and frothy salivation. Affected animals lay with the head arched back and the legs paddling. The heart rate can approach 150 beats/min, and the heartbeat is often audible without a stethoscope. Respiratory rate approaches 60 breaths/min, and rectal temperature can approach 40.5° C

(105° F) as a result of the excessive muscular activity. The eyelids flutter, and there is usually marked nystagmus. Animals may get up after several minutes and repeat these convulsive episodes several times before they finally die. Hypomagnesemic tetany in calves is clinically similar to that in adults and is often accompanied by moderate hypocalcemia.

Ewes are generally hypocalcemic and hypomagnesemic. Affected ewes are usually in the second to fourth week of lactation and are usually suckling more than one lamb. Affected ewes are generally depressed, stand with their heads down, and are reluctant to move. As hypomagnesemia and hypocalcemia progress, the animals develop tetany and clonic convulsions just as in cattle. The clinical signs in goats are similar to those observed in cattle.

Cerebrospinal fluid (CSF) Mg concentrations below 1 mg/dL are responsible for the clonic convulsions seen in animals with hypomagnesemic tetany. Blood samples obtained during or shortly after an episode of tetany may have near-normal levels of Mg as a result of muscle damage and leakage of Mg from intracellular pools. CSF Mg concentration will remain low during tetany and also can be a reliable indicator of Mg status for up to 12 hours after death. Vitreous humor Mg concentrations below 1 mg/dL are also found in animals with tetany and can be a reliable indicator for 24 to 48 hours after death, provided that environmental temperatures have not exceeded 23° C.[364] Aqueous humor has not proved a reliable sample.

1374 1375

41.1.7.5.4

Treatment of Hypomagnesemia

Animals exhibiting hypomagnesemic tetany need immediate treatment. This will require administering 1.5 to 2.25 g of Mg intravenously in the adult cow. Most of the commercially available intravenous solutions used to treat milk fever supply 1.5 to 4 g of Mg, usually as the chloride, borogluconate, or hypophosphite salts of Mg. Response to therapy can be disappointing, and success is related to the interval between onset of tetany and treatment. Cows should not be stimulated to rise for at least 30 minutes after treatment, to avoid initiating tetany and convulsions. Cattle that recover do so approximately an hour after treatment, which is the time it takes CSF Mg concentration to return to normal. Many of these cows will relapse and require further treatment within 12 hours.

The rate of relapse can be reduced using orally administered Mg salts once the animal has regained good swallowing reflexes (to avoid aspiration pneumonia). Administering a slurry of 100 g of Mg oxide in water intraruminally or by drenching can be effective. This provides approximately 50 g of Mg to the animal. Adding 50 g of Ca carbonate, 100 g of dicalcium phosphate, and 50 g of sodium chloride may enhance the effectiveness of the slurry, especially if hypocalcemia and hypophosphatemia accompany the hypomagnesemia. Alternatively, 200 to 400 mL of a 50% Mg sulfate solution can be administered by drench. Mg sulfate is more available for absorption than Mg oxide. If hypomagnesemic tetany has occurred in one cow or ewe in a herd or flock, steps should be taken immediately to increase Mg intake in other members of the herd to prevent further losses. Administering an additional 10 to 15 g of Mg per pregnant cow, 20 g of Mg per lactating beef cow, and 30 g of Mg per lactating dairy cow daily, usually in a grain mix, will often prevent further hypomagnesemic tetany cases. Ewes and does can be treated with ⅛ of these formulas. The problem with prevention is ensuring the extra Mg gets into the animal, especially when working with animals at pasture.

41.1.7.5.5 Prevention

41.1.7.5.5.1 USING OTHER TRANSPORT MECHANISMS TO ABSORB DIETARY MAGNESIUM

The active transport mechanism for Mg absorption across the ruminal wall is critical to the survival of the animal when dietary Mg concentration is less than 0.25%. Unfortunately there are several known factors, such as dietary K, and several unknown factors that prevent this pathway from functioning well. A second pathway for absorption of Mg exists and operates only at high ruminal fluid Mg concentrations. At high ruminal Mg concentration the Mg will flow down its concentration gradient into the extracellular fluids of the cow. This passive transport mechanism is not subject to inhibition by K and is subject only to the concentration of Mg in solution in the rumen.[362]

The concentration of Mg in ruminal fluid required to use concentration gradient—driven absorption of Mg is at least 4 mMol/L. The minimum level of Mg required in the diet to use this pathway in order to prevent negative Mg balance in the face of high K levels in ruminants is approximately 0.35%.[365] Mg content of the close-up dry cow ration and the early lactation ration should be between 0.35% and 0.4% as insurance against the possibility that the active transport processes for Mg absorption are impaired.

41.1.7.5.5.2 ASSESSING MAGNESIUM STATUS AT PARTURITION

PTH causes increased renal tubular reabsorption of Mg. The kidneys excrete less Mg, increasing blood Mg in the typical milk fever cow. However, if dietary Mg is insufficient or ruminal absorption of Mg is impaired, the blood Mg concentration will be below the normal renal threshold for Mg (1.85 mg/dL in cattle) and almost no Mg will appear in the urine. The animal should be considered abnormal for Mg. Sampling the blood of several cows within 12 hours of calving is a simple, effective index of Mg status of the periparturient cows. If serum Mg concentration is not at least 2 mg/dL in 9 of 10 cows sampled, it suggests inadequate dietary Mg absorption from either lack of dietary Mg or interferences with absorption. This same test can be used in the first weeks of lactation to see if the lactating cow diet is providing adequate Mg to the animal. This can be important, as hypomagnesemia may limit productivity of lactating cows as well as contributing to hypocalcemia in the herd.

41.1.7.6 PHOSPHORUS

Traditionally, *phosphorus* in clinical medicine is abbreviated as P, although it should be understood by the reader that the biologically relevant form of phosphorus is actually inorganic phosphate, not elemental phosphorus. P is a component of phospholipids, phosphoproteins, nucleic acids, and energy-transferring molecules such as ATP. P is an essential component of the acid-base buffer system. It is second only to Ca as a major component of bone mineral, with the skeleton of a 600-kg cow containing approximately 3.9 kg of P.

41.1.7.6.1 Phosphorus Homeostasis

Plasma P concentration is normally 4 to 8 mg/dL. Approximately 1 to 2 g of P are present in the plasma inorganic P pool, and 4 to 7 g of P in the extracellular P pool, of a 500-kg cow. Intracellular P concentration is approximately 78 mg/dL, and total body intracellular P content is approximately 155 g,

with 5 to 6 g located within erythrocytes. Maintaining the extracellular P pool involves replacing P removed for bone and muscle growth, endogenous fecal loss, urinary P loss, and milk production with P absorbed from the diet or reabsorbed from bone. During late gestation, fetal skeletal development can withdraw up to 10 g of P per day from the maternal P pools. Approximately 0.3 g of P is incorporated into each kilogram of body tissue (muscle) gained during growth of the animal. Production of milk removes from the extracellular pool approximately 0.9 g of P per kilogram of milk produced. Salivary secretions remove between 30 and 90 g of P from the extracellular P pool each day.[353] Factors affecting salivary phosphate secretion include the time spent ruminating (chewing activity) and the PTH status of the animal. PTH stimulates parotid salivary P secretion and can increase salivary phosphate concentrations twofold to threefold.[366] Salivary phosphate secretions help buffer the rumen and supply ruminal microbes with a readily available source of P necessary for cellulose digestion. Most of the salivary phosphate secreted is recovered by intestinal absorption. However, even on low-P diets, a minimum of 5 g of secreted P per day is not recovered and is lost to feces. Urinary P loss is usually between 2 and 12 g/day. Bones of a 600-kg cow contain approximately 4 kg of P, some of which can be withdrawn and returned to the blood during osteoclastic resorption of bone.

1375

1376

Ruminal microbes are able to digest phytic acid, so most of the phytate-bound P, the form of up to 70% of P in plants, is available for absorption in ruminants. P is primarily absorbed in the small intestine via an active transport process that is responsive to 1,25-dihydroxyvitamin D. Intestinal P absorption efficiency can, in theory, be upregulated during periods of P deficiency, as renal production of 1,25-dihydroxyvitamin D can be directly stimulated by very low plasma P. However, the plasma P level must reach very low levels (<1 to 2 mg/dL) to stimulate increased renal production of 1,25-dihydroxyvitamin D. Plasma P concentrations are generally well correlated with dietary P absorption. P absorbed in excess of needs is excreted in urine and saliva.

PTH, secreted during periods of Ca stress, increases renal and salivary excretion of P, which can be detrimental to maintenance of normal blood P concentrations. This is one reason that hypocalcemic animals tend to become hypophosphatemic. PTH could conceivably increase blood P concentration because it stimulates bone mineral resorption. Also, because PTH stimulates the kidney to produce 1,25-dihydroxyvitamin D, it can increase the efficiency of intestinal phosphate absorption. However, it must be remembered that PTH is secreted primarily in response to hypocalcemia, not hypophosphatemia.

41.1.7.6.2

Hypophosphatemia, Pregnancy Toxemia, and Downer Cows

Beef cows and ewes fed a diet marginal in P will have a chronic hypophosphatemia of 2 to 3.5 mg/dL. In late gestation, plasma P can decline precipitously as the growth of the fetus accelerates and removes substantial amounts of P from the maternal circulation. These animals often become recumbent and are unable to rise, though they appear fairly alert and will often eat feed placed in front of them. Cows and ewes carrying twins are most often affected. Plasma P concentration in these recumbent animals is often less than 1 mg/dL. The disease is often referred to as *pregnancy toxemia* and is usually complicated by concurrent hypocalcemia, hypomagnesemia, and in some cases hypoglycemia. Diets that are marginal in P are generally indicative of diets that are marginal in energy, because grains are usually very good sources of P.

At the onset of lactation in the dairy cow, the production of colostrum and milk draws large amounts of P out of the extracellular P pools. This alone often causes an acute decline in plasma P levels. In addition, if the animal is also developing hypocalcemia, PTH will be secreted in large amounts, increasing urinary and salivary loss of P. In dairy cows, plasma P concentrations routinely fall below the normal range at

parturition, and in cows with milk fever plasma P concentrations are often 1 to 2 mg/dL. Plasma P concentrations usually increase rapidly after treatment of the hypocalcemic cow with intravenous Ca solutions. This rapid recovery is caused by reduction in PTH secretion, which reduces urinary and salivary loss of P. Administration of Ca generally causes resumption of gastrointestinal motility, which allows absorption of dietary P and reabsorption of salivary P secretions that were sequestered within the rumen.

Some dairy cows that develop acute hypophosphatemia do not spontaneously recover normal plasma P concentration. This is sometimes the case in cows that are classified as downer cows. This syndrome often begins as milk fever, but unlike the typical milk fever cow, in these cows the plasma P remains low (<1 mg/dL) despite successful treatment of the hypocalcemia. Protracted hypophosphatemia in these cows appears to be an important factor in the inability of these animals to rise to their feet, but why plasma P remains low is unclear. In some cases the inability to absorb the salivary phosphate is secondary to poor ruminal motility, but not in all cases. Excessive cortisol secretion could also drive blood P concentration down, probably by forcing extracellular P inside cells. Treatment of cows with phosphate-containing solutions can effect a recovery in some animals. For oral treatment, the dose is 50 g of P supplied in a 200-g monosodium phosphate drench. Intravenous treatment consists of 6 g of P supplied by 23 g of monosodium phosphate dissolved in 1 L of saline. Oral treatment restores normal blood Pa a little more slowly than intravenous treatment, but the effect lasts much longer.[367] If depletion of intracellular P stores is also involved in the downer syndrome, it seems likely that intravenous treatment alone simply does not supply enough P to replenish intracellular stores of P.

The hypophosphatemic downer cow syndrome does not appear to be caused by low P diets, as affected cows are often receiving diets containing 0.4% dietary P. The best preventative measure seems to be to avoid development of hypocalcemia.

41.1.7.6.3

Chronic Phosphorus Deficiency

P deficiency is fairly common in grazing ruminants. Plant growth in arid climates or on tropical soils is often limited by poor soil P content or availability. Although P content of the immature plant may be suitable (0.3% P on a DM basis) the mature dry plants often contain less than 0.15% P, which can lead to P deficiency in ruminants forced to subsist on these forages. With the exception of rickets and postparturient hemoglobinuria, the clinical problems associated with P deficiency are general and nonspecific. They can include an unthrifty appearance, reduced feed intake, pica, reduced rate of gain, and reduced milk production.

41.1.7.6.3.1

OCCURRENCE

The most common of the P deficiency syndromes is the unthrifty cow that grows slowly, milks poorly, and is infertile. In arid areas of the world with inferior soil quality, infertility and poor growth resulting from inadequate P intake affects nearly all animals. Beef animals grown in these areas may routinely require 3 or more years to reach market weight. Brood cows often calve only every other year. In more temperate areas, P deficiency can develop in animals grazing overly mature forages or crop residues, such as corn stalks. Cows subsisting on forages that are low in digestibility are at risk for developing P deficiency unless supplemented. Increasing awareness of the environmental problems associated with P content of animal wastes and increasing expense of P supplements may encourage producers to feed diets marginally sufficient in P.

Sheep can, in some instances, be successfully raised on pasture that has been associated with P deficiency in cattle, suggesting that sheep are slightly more resistant to P deficiency syndromes than are cattle. This may simply reflect the higher intake per kilogram of body weight of sheep and their habit of selecting the less mature plants, which are generally higher in P.

41.1.7.6.4

Rickets and Osteomalacia

Rickets is a disease of young, growing animals in which the cartilaginous matrix at the growth plate and the osteoid matrix formed during bone remodeling fail to mineralize. In adults (no active growth plates), the term *osteomalacia* is used to describe the failure of osteoid matrix to mineralize. Ca and phosphate ions come together in a ratio of 10 Ca ions to 6 phosphate ions at the point of mineralization of the bone cartilage or osteoid matrix. Bone ash content varies somewhat with the bone examined but is generally 57% to 62% of bone dry weight, with 36% Ca and 17% P in adult animals. Failure to supply P in the diet will result in low plasma P concentrations that will not support the mineralization process, and the bone matrices will fail to mineralize. Bone ash, as well as total P and Ca content, will be below normal.

1376

1377

Low plasma Ca concentrations (arising from vitamin D deficiency or severe Ca deficiency) can also result in failure to mineralize bone matrices. Bone ash is reduced, and the bones of young animals become "rubbery," bending without breaking. Joint surfaces are often eroded, contributing to lameness in affected animals.

In principle, Ca deficiency differs from P deficiency in that normal osteoid is formed but fails to mineralize in P deficiency, whereas in Ca deficiency the normal osteoid is either not formed at all (osteoporosis) or replaced by fibrous tissue. In vitamin D deficiency it is common to see mixed lesions (osteomalacia, osteoporosis, and fibrous osteodystrophy) all in the same bone. Vitamin D deficiency also seems to reduce secretion of type X collagen by the chondrocytes within the growth plate and somehow prevents the programmed cell death of chondrocytes within the zone of provisional calcification, a requirement for bone formation.

41.1.7.6.5

Chronic Moderate Hypophosphatemia

Animals fed diets containing less P than necessary to meet physiologic needs will develop hypophosphatemia and all the physiologic consequences of failure to grow, inappetence, and unthriftiness. Milk production, but not P content, will decline. Impaired reproduction has often been attributed to "P deficiency." However, in most cases in which cows develop P deficiency the situation is complicated by concurrent energy deficiency, likely the direct cause of the reproductive failure.

Unfortunately the belief that "marginal" dietary P contributes to reproductive inefficiency has been used as justification for feeding diets that are much higher in P than is required. Wu and Satter[368] present convincing evidence that high-producing cows perform well in terms of milk production and fertility when fed diets containing 0.37% to 0.40% P.

41.1.7.6.6

Postparturient Hemoglobinuria

Intravascular hemolysis, anemia, and hemoglobinuria are occasionally reported during the first 6 weeks of lactation. Cows that have been treated for ketosis seem at greater risk for developing postparturient hemoglobinuria. Many, but not all, cows that develop this syndrome are hypophosphatemic. Severe

hypophosphatemia is postulated to depress the ability of erythrocytes to produce ATP> Glyceraldehyde-3-phosphate dehydrogenase, a key enzyme in glycolysis, requires inorganic phosphate as a cofactor. Without sufficient ATP to power sodium pumps, the intracellular sodium concentration rises, the cells become more rigid, and as a result they rupture as they pass through the capillary beds. However, hypophosphatemia alone is rarely sufficient for increased red blood cell fragility. Often these cows are on diets that are also deficient in selenium, copper, and energy. In light of these observations, it is likely naive to suggest that the cause of postparturient hemolysis is hypophosphatemia alone (Table 41-9).

Table 41-9 Diagnosing Acute and Chronic Macromineral Insufficiency or Imbalance in Ruminants*

Mineral	Tissues to Use	Normal	Subclinical Deficiency	Clinical Deficiency
Calcium (acute)	Serum, plasma (mg/dL)	8–10.5	5.5–7.5	<5.0
Calcium (chronic)	Serum, plasma (mg/dL)	8.0–10.0	8.0–10.0	6–10
	Rib bone ash (% Ca)	37–39	35–37	<35
	Urine (mg/dL)	2	0.5–1.5	<0.1
Phosphorus (acute)	Serum, plasma (mg/dL)	4–6	2–4	<1.2
Phosphorus (chronic)	Serum, Plasma (mg/dL)	4–6	3–4	<3.0
	Rib bone ash (% P)	17–20	15–17	<12
Magnesium (acute)	Serum, plasma (mg/dL)	2.0–2.3		<1.1
	Vitreous humor (mg/dL)	1.9–2.5	1.5–1.85	<1.5
	Urine (mg/dL)	10–25	2–5	<0
	Cerebrospinal fluid (mg/dL)	2–2.5		<0.5
Magnesium (chronic)	Serum, plasma	2.0–2.3	1.6–1.9	<1.5

* The tissue needed to ascertain acute problems is intended to guide diagnosis of the initial cause of recumbency in downer cows.

41.1.7.7

HYPOKALEMIA SYNDROME IN CATTLE

NICOLAS SATTLER

Based on reports available in the literature, hypokalemia syndrome in cattle can be defined as presence of flaccid paralysis, recumbency, abnormal neck position, and serum potassium concentration below 2.5 mmol/L.

41.1.7.7.1

Occurrence

Hypokalemia is a frequent biochemical finding in cows presented with anorexia and gastrointestinal stasis.[369] It is often mild (>3 mmol/L) and not associated with obvious clinical signs in ruminants. Hypokalemia syndrome is a rare clinical condition reported in a total of 25 animals in three studies.[370–372] Lactating dairy cows appear to be at a higher risk, but the syndrome has also been described in calves and heifers.

41.1.7.7.2

History

Lactating dairy cows less than 60 days in milk (DIM) constitute the majority of cases in the literature. Any disease causing significant anorexia for 1 week or more, particularly infectious disease, is a risk factor.[371] Repeated administration of isoflupredone acetate is reported in most cases, for treatment of either acetonemia in lactating cows[370] or infectious respiratory disease in calves and heifers.[371] In one case, repeated off-label intramammary administration of isoflupredone acetate preceded hypokalemia syndrome. Multiple doses of dextrose and insulin are also reported to be risk factors.[370] Intravenous fluid administration for 2 days or longer without serum biochemistry followup has been documented in two cases of calves with severe neonatal diarrhea.

1377

1378

In most cases recumbency caused by hypokalemia syndrome was not the initial event but rather occurred during the evolution of another disease such as acetonemia or infectious disease. Moreover, recumbency was not always the presenting complaint.[371] Some animals first manifested anorexia, reduced fecal output, kyphosis, and reluctance to move. However, evolution to severe paresis and decubitus occurred rapidly in all these cases.

41.1.7.7.3

Clinical Signs

In the early stages of the syndrome, absence of feces, paretic gait, kyphosis, inability to stand for a long time, and tachycardia are observed. Sometimes an abnormal neck posture is evident before recumbency. The typical case presentation of hypokalemia syndrome includes decubitus, S-shaped neck, abnormal feces and ruminal motility, abnormal appetite, and tachycardia with or without arrhythmia. Decubitus is a result of flaccid paralysis: the tail has little to no tonus and is held in an abnormal position, resistance to all manipulations is weak, and the cow is unable to raise her head. It is not rare to observe that the animal eats and drinks willingly if food and water are provided near the mouth. Abnormal appetite therefore may be partly caused by an inability to move the head to reach food and water. The neck is carried in an S-shaped and twisted fashion that differs from that of the hypocalcemic cow. The neck is never fixed in this abnormal position. When moved there is no resistance, and if the head is placed in an anatomically correct position there is an odd feeling of luxation. As soon as the head is not held, the neck resumes the abnormal S-shaped position, deviating to either direction. This neck posture may precede decubitus and persist after decubitus has resolved. Cardiac arrhythmias (Fig. 41-20) also accompany hypokalemia syndrome and may be ventricular (ventricular tachycardia, accelerated escape ventricular rhythm) or supraventricular (atrial fibrillation) in origin.

Fig. 41-20 Electrocardiograms. *Panel 1,* Electrocardiograms of a cow with hypokalemia syndrome before treatment (base-apex, 25 mm/sec, 1 cm = 1 mV). Potassium serum concentration was 2 mmol/L. **A,** Note the ventricular escape rhythm: normal heartbeat and more than five ventricular QRS complexes. **B,** Note the flattened T waves and increased intervals. *Panel 2,* Electrocardiogram of a cow with hypokalemia syndrome after treatment (base-apex, 25 mm/sec, 1 cm = 1 mV). Potassium serum concentration was 4 mmol/L. Note the normal T waves and intervals.

Hypokalemia syndrome is most often the consequence of a concomitant disease or treatments administered. Fever and acetonemia are the most frequently associated problems. The identification of the concomitant disease(s) is essential for accurate prognosis and treatment.

41.1.7.7.4

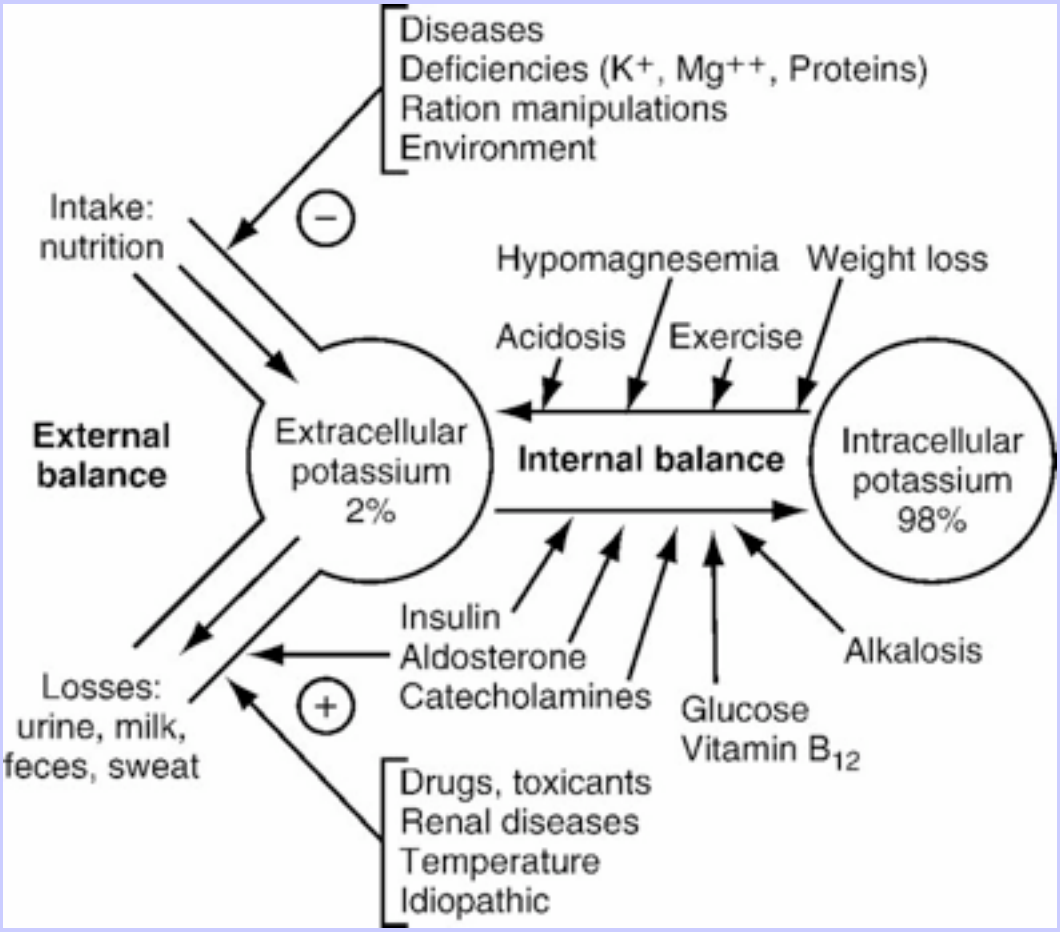
Etiology

Hypokalemia may result from an imbalance of the internal or external potassium balance or both (Fig. 41-21).[369,370,373–376] Internal potassium balance is determined by exchanges between extracellular and intracellular compartments, whereas external balance is a result of systemic intake and losses. Currently, except for cases with documented repeated isoflupredone acetate administrations, the exact determinants causing hypokalemia syndrome in cows are not known.

1378

1379

Fig. 41-21 Potassium balances and major determinants in cattle. Adapted from Brobst D: *J Am Vet Med Assoc* 188:1019, 1986.



At present, because of the limited data available, it is not possible to determine if hypokalemia syndrome cases are mainly a result of potassium depletion, internal imbalance, or both. The prolonged inappetence observed before hypokalemia, along with the amount and duration of potassium needed for treatment, suggests potassium depletion is significant. Serum potassium concentration is a poor indicator of the potassium status of the organism because 98% of whole body potassium is located in the intracellular compartment.[374,377] Determination of intracellular potassium concentration in erythrocytes or muscle cells

could be a more accurate way to assess potassium depletion.[377,378] At present these data are not available for hypokalemia syndrome cases.

As a result of the potent mineralocorticoid activity of isoflupredone acetate, cases associated with its administration show both internal and external potassium balance abnormalities (see Fig. 41-21).[376] Repeated doses can reduce blood potassium concentration by 70%.[379] In a small experimental study (N = 9), we were able to reproduce the syndrome by combining food restriction and multiple doses of isoflupredone acetate in lactating dairy cows.[380] The use of this steroid could also complicate the treatment of the hypokalemia syndrome by increasing the renal losses of potassium. Based on current knowledge, use of isoflupredone acetate in the anorectic, acetonemic cow that has received dextrose, with or without insulin, should be restricted to one administration at the labeled dosage. Hypokalemia syndrome has also been reported with dexamethasone administration, although it is a less potent mineralocorticoid.[372]

In noniatrogenic cases the relationship between protracted disease and severe hypokalemia may be explained by a decrease in potassium intake (anorexia) with increased release of catecholamines caused by stress (see Fig. 41-21). Alternatively, renal potassium adaptation[381] may be responsible for the potassium loss. Animals chronically fed a high-potassium diet are able to survive the high potassium load due to increased renal losses. These increased losses persist when potassium intake is suddenly reduced. Renal adaptation (reduction of urinary potassium excretion) takes 24 to 48 hours to occur, thus creating a potassium depletion.[381] Because of a forage-based diet, lactating dairy cows may eat more than 10 times their daily potassium requirement, causing high urinary potassium excretion.[371] Therefore these cows appear to be at risk for potassium depletion because of delayed renal adaptation when potassium intake is abruptly reduced. This model cannot explain why some cows develop the syndrome when exposed to these conditions but others do not.

Other factors known to promote significant hypokalemia have not been documented in cows with hypokalemia syndrome, such as anomaly of the aldosterone system, diuretic (particularly furosemide) abuse, nephropathy (proximal or distal tubular renal acidosis), or severe diarrhea. Diarrhea with protracted reduced potassium intake, increased losses, and internal potassium imbalance resulting from acidosis has been associated with hypokalemia syndrome in calves.[371] Error in fluid administration causing increased urinary losses of potassium along with return to a normal internal potassium balance can further exacerbate hypokalemia in diarrheic calves.

41.1.7.7.5

Pathophysiology

Potassium is the most important intracellular cation.[382] The gradient between the potassium concentrations of the intracellular and extracellular compartments is the determinant of the resting cellular membrane potential and plays a role in the formation and transmission of action potentials.[383] Therefore, clinical signs reported in cattle and other species with severe hypokalemia are multisystemic. Moreover, structural consequences in the myocardium[373] and the muscle cells have been reported in cattle.[370,371]

Dysrhythmia and electrocardiographic changes were present in 50% of cases in one study.[371] The arrhythmogenic electrical activity changes implicated in hypokalemia include the following: hyperpolarization of the cardiac cell resulting in spontaneous automatic activity, slow conduction caused by increased difference between resting membrane potential and threshold potential, increased action

potential duration as a result of slow repolarization, depressed fast responses because of higher membrane potential when a slow repolarizing cell is stimulated, slow responses in fibers normally exhibiting fast responses, and conduction block.[384] These electrical events alone or in combination with structural changes such as necrosis can induce the atrial and ventricular arrhythmia observed.

Pathophysiology of cardiac and muscle necrosis caused by potassium depletion includes (1) ischemia caused by lack of vasodilatation during muscle cell contraction, resulting from absence of potassium release into the extracellular space, and (2) glycogen deficiency resulting from impaired glycogen synthesis.[376,385] Muscle lesions compatible with hypokalemic myopathy have not been consistently documented.[370–372] It is presently not known if the presence of hypokalemic myopathy is necessary to the occurrence of the clinical signs observed in the bovine syndrome or if it is a prognostic determinant.[370,371]

41.1.7.7.6

Diagnosis and Ancillary Test Results

Initial presentation of hypokalemia syndrome (intestinal ileus, abnormal gait) could mimic an intestinal syndrome. History may allow distinction between these conditions. Hypokalemic syndrome often follows or is concomitant with a long disease, in contrast with the usual acute evolution of an intestinal syndrome. According to the results of a small experimental study,[380] potassium fractional urinary excretion (FE_K) could be a useful tool in the medical management of a cow suspected to be developing bovine hypokalemia syndrome. In this study, FE_K was abnormally high in the presence of severe hypokalemia 12 to 24 hours before manifestation of clinical signs.

According to our experience the clinical signs of a twisted, S-shaped neck associated with flaccid paralysis as described earlier are almost pathognomonic. Other conditions that could be included in the differential diagnosis are hypocalcemia, botulism, tick paralysis, and myelopathy (cervical spinal trauma, cervical osteomyelitis). Conditions like listeriosis, vertebral malformations, luxations, fractures, and torticollis can be associated with abnormal neck position but not flaccid paralysis and absence of pain during manipulations. Hypokalemia syndrome, even if rare, should be included in the differential diagnosis of hypocalcemia, particularly when response to calcium administration is not normal.

Confirmation of the clinical diagnosis requires serum biochemical analysis. To date, all published cases of bovine hypokalemia syndrome have been associated with serum K^+ concentrations less than 2.5 mmol/L. Aside from hypokalemia, moderately elevated AST and creatine kinase (CK) activity (median value of 171 and 1564 IU/L respectively[371]), severe metabolic hypochloremic alkalosis (median value [TCO_2] = 41.5 mmol/L, [Cl^-] = 86.9 mmol/L[371]), and mild hyperglycemia (median [glucose] = 6.05 mmol/L[371]) are observed in the majority of published cases.

1379 1380

Lumbar muscle biopsy (between L2 and L5) is a way to differentiate primary hypokalemic myopathy from secondary myopathy caused by decubitus. Determination of the serum creatine kinase MB isoenzyme (CK-MB) activity could help to detect myocardium damages. Detection of myopathy in epaxial muscles and/or myocardium at necropsy is not diagnostic if potassium depletion or hypokalemia is not documented.

Some authors have suggested that electrocardiographic changes could be used to detect a potassium-depleted status, irrespective of the serum potassium concentration.[386] A method of determining both the internal and external potassium balances simultaneously in dairy cows has been presented.[378] In this study,

ingested potassium, milk potassium concentration (LK), and FE_K defined the potassium external balance. Serum potassium concentration (SK) and red blood cell potassium concentration (CIEK) defined the potassium internal balance. Significant variations were detected throughout the day for CIEK, LK, and FE_K.[378] Therefore, in order to monitor potassium balances over time, samples should be collected at the same time each day.

41.1.7.7.7

Treatment

Nursing care is of primary importance to prevent complications such as mastitis or myopathy caused by prolonged decubitus; to maintain alimentation by providing food and water near the mouth; and to provide favorable conditions for the cow to get up. The animal should be kept on clean and atraumatic bedding such as pasture, sand, or accumulated litter. It must be regularly milked and turned from one side to the other at least every 8 hours. Use of a flotation tank (Aquacow Rise System) is of great value once the serum potassium concentration has returned to normal range.

All other identified problems must be addressed, including dehydration, acetonemia, and infectious disease. Treatments for arrhythmias, other than potassium, were not given in the reported cases.

Specific treatment is mainly per os potassium chloride supplementation. Based on the published data and our experience, we recommend a total (per os and intravenous) KCl dose per day of 50 g/100 kg of body weight of cow. Intravenous administration should be reserved for dehydrated cows, as overhydration may worsen hypokalemia by increasing potassium renal losses. When potassium chloride is given IV, the rate should not exceed 0.5 mEq of K^+/kg/hour, to avoid high risk of cardiac toxicity. Serum potassium should be monitored twice daily to allow adjustment of the treatment regimen. Potassium supplementation is needed for an average of 5 days.[371]

The abnormal neck position can be the first and last clinical sign in the evolution of the hypokalemia syndrome. Other clinical signs usually disappear on average in 3 days, the same day potassium concentration typically returns to normal. Some degree of paresis may persist for 2 to 3 days after return to normokalemia. We recommend continued potassium supplementation for 1 or 2 days after the return to normal clinical state and appetite. Increased renal potassium losses are promoted by the high quantity of potassium given during the treatment. In our experience it is important to decrease potassium supplementation slowly to avoid potassium depletion caused by delayed renal adaptation to the lower potassium diet. For example, 25 g of KCl per 100 kg of cow may be given the day after return to normokalemia, then 12.5 g of KCl per 100 kg of cow for 2 more days.

Because potassium depletion is a primary cause of myopathy, it is important *not* to try to raise the cow before hypokalemia has resolved. This emphasizes the importance of good nursing care and regular decubitus side changes. Once serum potassium concentration reaches the normal range, a water flotation tank is the best system to manage the recumbency.

41.1.7.7.8

Prognosis

The survival rate was very different in the two series of cases reported: 2 of 8[370] versus 11 of 14.[371] The prognosis may be affected by the age, concomitant disease, initial potassium depletion degree, presence and severity of hypokalemic myopathy, or treatments received.[369] The quality of the supportive care is probably a major determinant of the outcome, as for any downer cow. In the field, because of time and

energy needed from the owner, our experience warrants a guarded prognosis. The availability of a flotation tank appears a significant positive prognostic factor.[371,372]

41.1.8 BOVINE SOMATOTROPIN

V. MICHAEL LANE

AURORA VILLARROEL

Somatotropin, also known as *growth hormone* (GH), is a peptide hormone produced in the anterior pituitary gland of all animals and is an important endocrine factor for normal growth of all tissues[387] and lactation in mammals. It is released under the influence of GH-releasing factor and inhibited by somatostatin. High-producing dairy cattle have naturally elevated circulating levels of endogenous somatotropin.[388,389] The lactogenic effect of somatotropin was first discovered in 1928 after rabbits were injected with crude extracts of anterior pituitary glands,[390] and its effect in lactating dairy cows was first reported in 1937.[391] Since the 1980s, recombinant DNA manipulations allowed large-scale production of purified somatotropin.[392,393] Because the use of several synonyms of somatotropin throughout the literature can be confusing, this chapter will use *GH* to refer to natural somatotropin and *rBST* to refer to recombinant BST. It has been shown that rBST has biologic activity similar to that of bovine GH.[394] Four variants of bovine GH have been reported, according to whether it has 190 or 191 amino acids (additional phenylalanine in *N*-terminal) and either valine or leucine in position 127.[395,396] The genetic determination of the amino acid present in position 127 seems to be breed-specific. Homozygosity for leucine is more frequent in larger breeds such as Holstein and Brown Swiss (85% and 100%, respectively) compared with smaller breeds such as Jersey and Ayrshire (31% and 59%, respectively).[396] This variation may account for differences in milk production.

Four recombinant analogues have been developed[397,398] and differ in 0 to 9 amino acids from GH. Methionyl-rBST (leucine variant with 190 amino acids)[399] was approved for use in lactating dairy cows in the United States in November 1993[400] and is available for commercial use in more than 20 countries, including Mexico, Brazil, South Africa, South Korea, and Russia. The release of rBST for commercial use provides new opportunities and challenges for the dairy herd manager, veterinarian, and nutritionist.

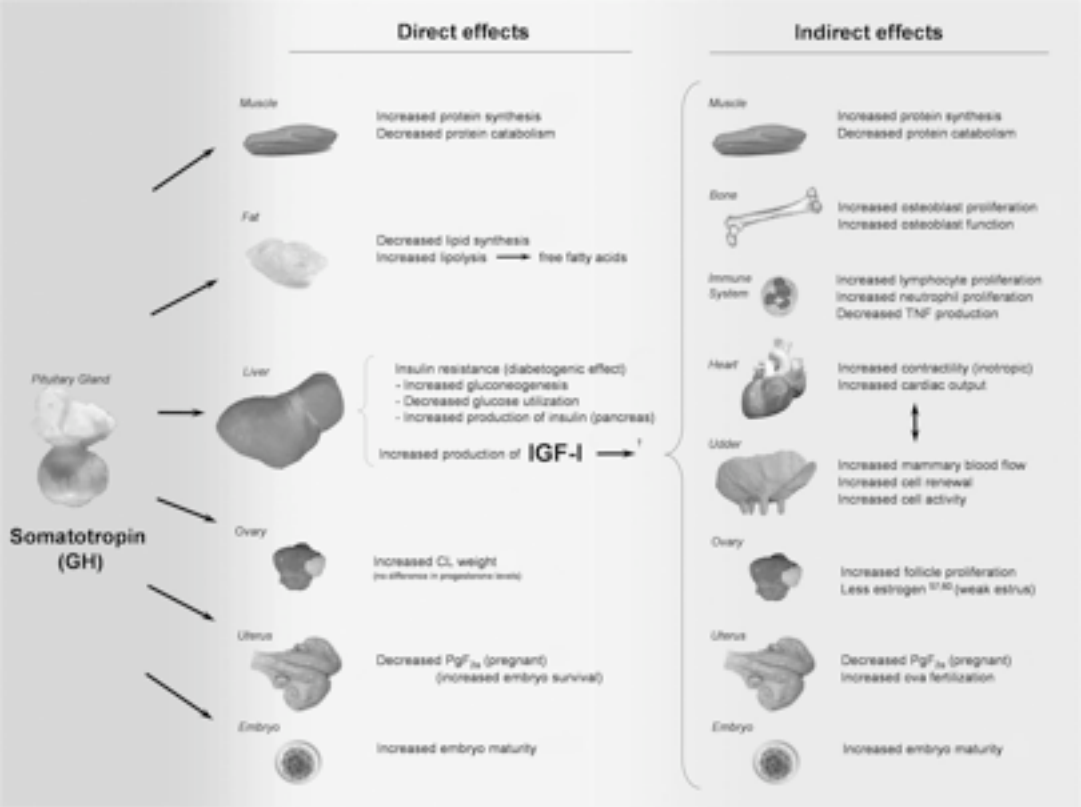
41.1.8.1 PHYSIOLOGY OF GROWTH HORMONE

Physiologic concentrations of GH in blood are secreted in a pulsatile pattern and vary throughout the day, being lowest after midnight and highest during the day (diurnal variation) both in humans and in dairy cattle. [387,401] Baseline levels and frequency and intensity of the secretory pulses of GH are highest during the first week of age and then decrease with age.[389,402,403] Apparently, GH levels in neonates are not influenced by colostrum intake, as evidenced by a study in which calves that received their first colostrum 24 hours after birth did not differ in serum GH levels from calves that received their first colostrum feeding at 2 hours, 6 hours, or 12 hours after birth.[404] Physiologic GH levels are heavily influenced by gonadotropin hormones; intact bulls had higher baseline levels and higher frequency and intensity of pulses of GH as compared with steers, which in turn had higher levels and pulses than heifers (intact or ovariectomized).[405] In lactating cows, GH levels are highest during the postpartum period and gradually decrease as the lactation advances

and milk production decreases.[388,406–408] Blood concentrations of GH are naturally higher in high-production cows as compared with low-production cows,[389,408,409] even during the dry period.[388,406]

GH must bind to GH receptors located in specific tissues to exert its direct effects, one of which is the local secretion of somatomedins throughout many organs.[387,402,410] Of the four somatomedins identified to date, the type I insulin-like growth factor (IGF-I) is the most important.[387] IGF-I is found in serum attached to IGF binding proteins. It exerts its action when bound to IGF receptors on target tissues. The complete somatotropic axis consists of GH, GH receptors, IGF-I, IGF-I receptors, and IGF-I binding proteins. Fig. 41-22 depicts the target organs for GH action via direct effects of GH and indirect effects of IGF-I.

Fig. 41-22 Summary of direct and indirect effects of somatotropin in cattle.†IGF-I is produced in the liver and locally in many tissues throughout the body.



Overall, GH promotes increased cell size and mitosis in almost all tissues of the body that are capable of growing (directly or indirectly through the action IGF-I) and a shift in metabolism to use fat for energy in preference to carbohydrate and proteins, which are spared.[387,402] The immediate result of the increased use of fat as energy source for the body is a measurable rise in NEFA concentrations in blood.[387,402,410] Another direct effect of GH on the liver is to increase glucose synthesis.[387,402] GH stimulates the pancreas to secrete increased amounts of insulin, although a simultaneous IR is induced that results in a diabetogenic effect.[387] It

has been shown in humans and rats that an increase in serum FFAs impairs the action of insulin on tissue glucose use.[411,412] The effects of GH on liver, pancreas, and adipose tissue are direct because of the presence of multiple GH receptors in these tissues.

Muscle is affected directly by GH and indirectly by IGF-I. Both GH and IGF-I act on muscle cells to increase protein synthesis and decrease protein catabolism.[387,402] The net effects of the changes in muscle and fat metabolism are to increase lean body mass.[387,402] When rBST is administered to growing cattle, it has an anabolic effect [402,413–415] similar to that of steroid hormones[415] that seems to be a result of increased feed intake rather than an increased efficiency of feed conversion.[403] GH also has an effect on bone growth through the action of IGF-I, which increases osteoblast proliferation and function.[387,402] IGF-I also mediates an enhanced response to induced infection and endotoxemia through lymphocyte blastogenesis,[416] neutrophil proliferation,[417,418] and decreased levels of TNF.[419,420]

1381

1382

The most obvious outward manifestation of rBST administration in the lactating cow is an increase in milk production.[391,421,423] Other manifestations include changes in body composition, both positive and negative effects on reproduction, and proliferation of immune cells. These changes are achieved through an "orchestrated control" of the metabolic functions (homeorrhesis) to support the new physiologic state of higher milk production. Table 41-10 shows the short-term and long-term effects (after homeorrhesis) of rBST administration in lactating dairy cows. The use of rBST in lactating cows increases milk production through its effect on nutrient partitioning,[410] increased rate of cell renewal in the mammary gland,[424] and support of mammary cell function.[425] Although receptors for GH in the mammary gland were recently discovered,[426,427] bovine GH does not appear to have a direct galactopoietic effect on mammary tissue.[428,429] The galactopoietic effect of rBST has been reported to be indirect, through the action of IGF-I.[430,431] IGF-I is associated with increased mammary blood flow and enhanced mammary extraction of substrates.[430,432] The heart plays a major role in nutrient partitioning by increasing contractility and output, which increases blood flow to the mammary gland.[430,433,434] These actions are responsible for a higher persistency of milk production in rBST-treated cows (Fig. 41-23). The ultimate effect is the increased use of fat as an energy source to spare glucose and acetate for mammary gland lactogenesis.[430] This avoids excessive weight gain during late lactation as measured by BCS[422,435] but can also can result in weight loss when dietary energy is restricted.[436–438] The use of rBST does not cause significant changes in blood mineral levels.[431,439]

Table 41-10 Short-Term and Long-Term Effects of the Use of Subcutaneous Injections of 500 mg of rBST Every 14 Days in Lactating Dairy Cows

Target	Short-Term Effects	Long-Term Effects
Milk production	Increased, with peak on day 7–11 with a gradual decrease to baseline levels around day 14	Increased, following a typical downward trend in production as DIM increase, although with higher persistency than in untreated cows; no effect on production during the next lactation
Feed intake	No change	Increased, starting 4–10 weeks after the initial treatment to provide energy for the increased milk production
Energy balance	Decreased because of increased milk production and unchanged feed intake	Normal, as feed intake accommodates to higher milk production
Milk composition	Initial increase in fat % and decrease in protein, reflecting initial negative energy balance	Normal or slightly increased protein percentage
Reproduction	Positive influence because of increase in IGF-I levels in blood.	Negative influence of higher milk production and higher clearance rate of steroid hormones because of higher liver blood flow
Metabolism	Changes that reflect the state of initial negative energy balance: increased plasma levels of NEFA, insulin and glucose	After feed intake increases to adapt to the increased milk production, metabolic indices return to normal; lower NEFA and BHB plasma levels in the next lactation
Body condition	Decrease in fat content and therefore in body weight, especially if the negative energy balance is severe	Maintenance of healthier body condition (leaner body) during late lactation than in untreated cows
Health		
Mastitis	Improved response to infection due to a proliferation of immune cells	Tendency to increase the crude incidence of lameness, although it can be attributed to the higher risk normal for higher production; incidence by pounds of milk produced is decreased
Lameness	No change	Tendency to increase the crude incidence of mastitis, although it can be attributed to the higher risk normal for higher production
Ketosis	No change	Decreased incidence of ketosis in the postpartum period that follows the lactation in which cows were treated; attributed to a leaner body composition

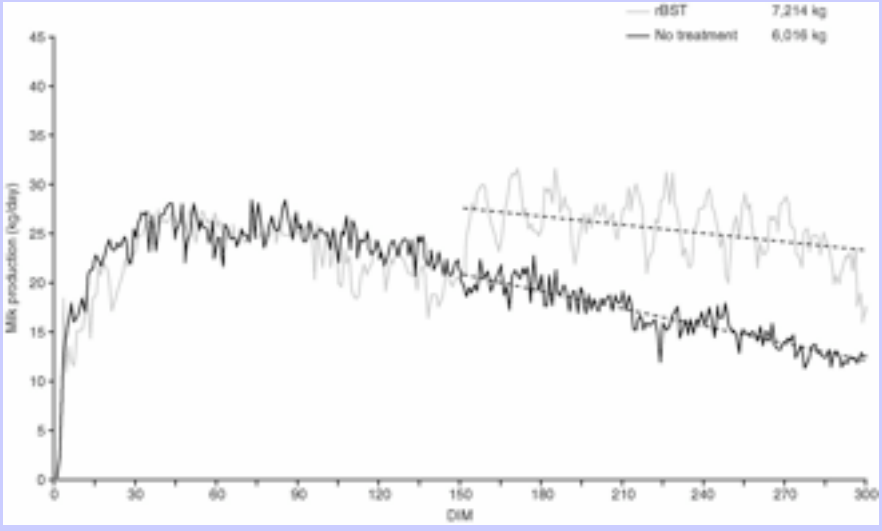
BHB, β-hydroxybutyric acid; *DIM,*days in milk; *IGF-I,* insulin-like growth factor; *NEFA,* nonesterified fatty acid.

Other effects of rBST in cows include direct and indirect effects on reproductive organs. GH receptors (direct effect) are found mostly in the ovary, primarily on the corpus luteum (CL), with nearly undetectable levels on follicles.[440,441] Cows treated with rBST had heavier CLs [442] but no difference in blood progesterone levels.[442–444] Other tissues with high expression of GH receptors, although not as abundant as in the CL, included (in decreasing order) myometrium, endometrium, and oviduct.[440] In vitro exposure of endometrial cells to rBST attenuated the production of phorbol ester—induced prostaglandin (PG) $F_{2\alpha}$; on the other hand, IGF-I increased its production.[445] Receptors for IGF-I in the reproductive organs were expressed primarily in the myometrium and less in the endometrium, ovary, and oviduct.[440] Although follicles did not show high expression of GH or IGF-I receptors, treatment with rBST increased follicle proliferation and recruitment.[443,444] The dominant follicles were larger but contained lower levels of estrogen.[443,446] Pregnant cows had higher expression of IGF-I receptors throughout the reproductive tract compared with nonpregnant cows, especially in the myometrium.[440] The embryo has receptors for both GH and IGF-I, and both peptides increase the rate of embryo maturation.[447–449] GH is additive to IFN-tau (produced by the embryo) in its effect of attenuating uterine production of $PGF_{2\alpha}$.[445] Therefore somatotropin may be an important factor for maternal recognition of pregnancy.

1382

1383

Fig. 41-23 Comparison of lactation curves of two first-lactation cows, one treated with rBST and one untreated, showing the cyclic response to rBST injection every 14 days and the improved persistency of milk production. The dips in the treated cow correspond to the administration of a new injection of rBST (every 14 days). Dashed lines represent average daily milk production. Note the variable response to different injections. From Lane VM, Villarroel A, unpublished data.



Half-life for important lactopoietic hormones is as follows[387]:

- Somatostatin: 3 minutes
- Insulin: 6 minutes
- GH: 20 minutes
- IGF-I: 20 hours

41.1.8.2

IMPACT OF SOMATOTROPIN ON MILK PRODUCTION

Many studies have reported a consistent effect of increased milk production after short- and long-term administration of rBST. Most trials are not directly comparable to one another because of the use of different somatotropin analogues, dosages, lengths of study, and intervals between doses used in the studies. These experimental trials have been conducted under differing feed conditions and show similar responses in milk production to treatment with rBST in pasture-based dairy cows,[450,451] stalled cows,[452,453] and cows fed a total mixed ration (TMR).[392,454] Studies show a wide range of increase in milk production (8% to 61%) over the baseline production before rBST administration. This range reflects individual cow variation in the response to rBST, and it has been recognized since the first trial in 1937 (pituitary extract) that some cows do not respond at all.[391,455] In general, larger responses were observed at higher doses of rBST,[436,437,456] although the dose response could be characterized as a negative exponential relationship: milk response per milligram of rBST is diminished at higher doses. Larger responses have been observed when rBST was administered daily (up to 61%)[453,457–459] as compared with administration at 14-day intervals (up to 31%)[422,453,460,461] or 28-day intervals (up to 18%).[392,454] Most of these studies with large responses reported the short-term effects of rBST supplementation, whereas long-term trials reported milk increases ranging from 11% to 29%.[422,435,451,462] Consistently higher responses (both in kilograms and percentages) occur in adult cows as compared with first-lactation heifers.[421,422,463] Furthermore, the effect of rBST use on milk production varies according to production level before rBST administration and stage of lactation, in that lower-producing cows seem to respond better than higher-producing cows,[463–465] and late-lactation cows respond better than early-lactation cows,[422,463] both in kilograms and percentages. Although Holstein cows have a higher response to rBST treatment than Jersey cows[437,465] the effective response (return on rBST investment) may be higher in Jerseys because of their higher milk solids.

In February 1994 the rBST named *sometribove* (zinc-methionyl BST, Monsanto) was first commercialized in the United States for use at a dose of 500 mg to be given every 14 days beginning at 57 to 70 days in milk (DIM) and continuing until the end of lactation.[400] Since then, multiple studies have been reported that are now comparable because of the uniformity of product and application. Production responses were reported in 176 control herds and 164 herds using sometribove in the Northeast United States for a period of 4 years before approval and 4 years after approval.[423] In this study, cows from herds using rBST produced an average of 894 kg more milk, 27 kg more fat, and 31 kg more protein during a 305-day lactation compared with control herds. A metaanalysis of data from 28 studies using various analogs of rBST reported a production improvement of 11.3% in primiparous cows and 15.6% in multiparous cows, equivalent to 3.03 and 4.36 kg/day, respectively, over control cows.[421] In another study[422] the reported average response to sometribove in 15 U.S. herds was 4.9 kg/cow/day with a wide range among herds (2.9 to 7.6 kg/cow/day),

corresponding to production increases that ranged from 11% to 31%.[423,450,453,460,461] Some trials conducted over multiple lactations have reported a lower response of cows treated in a second lactation[436,466–469]; however, all these trials used daily administration of rBST. Studies conducted using the approved 14-day interval application showed that previous treatment with rBST did not diminish milk production in subsequent lactations,[423,470] even in a study conducted over four lactations.[471]

Lactation graphs of cows responding to rBST administered at 14-day intervals show a cyclic response to treatment,[422,460,472] in which milk production started increasing on day 1 after injection, peaked on day 7 to 11, and then decreased until the next dose (see Fig. 41-23). The use of rBST does not practically alter milk components,[460,470,472] although minor changes in milk fat and protein have been observed in association with shifts in energy balance.[422,471,472] Cows with higher somatic cell counts (SCCs) before treatment can be expected to have a diminished response to rBST compared with cows with lower SCCs.[422]

41.1.8.2.1

Factors Limiting Response to Recombinant Bovine Somatotropin

Nutrition is the most important factor that can limit milk production response to rBST. Although short-term treatment with rBST increases milk production without increasing dry matter intake (DMI),[457,462] long-term treatment (4 to 10 weeks) results in increased DMI to compensate for the increased production.[437,458,462] Current nutritional standards for high-producing cows[473] meet requirements for rBST-treated cows, assuming emphasis is given to consistency of the ration and feed-bunk management. If ration inconsistency leads to indigestion and “off-feed” conditions, or if feed is periodically unavailable to the cow, DMI and therefore milk production will be reduced. These off-feed conditions may affect the response to rBST. McGuire and colleagues[474] found that after restriction of feed intake to lactating cows, plasma concentrations of IGF-I were markedly decreased, indicating that the stimulatory effects of rBST on lactation would not be observed in underfed cows. In this study, underfeeding of cows resulted in a marked decrease in milk production despite rBST treatment. Radcliff and co-workers[475] have shown that DMI partially controls expression of GH receptor mRNA and that cows on feed restriction had lower receptor activity for at least 1 week after ad libitum feed was restored.

Heat stress is another important factor affecting the response of milk production to rBST. Trials conducted under hot humid conditions[450,476,477] suggest that milk production response to rBST may be more variable than that obtained under temperate conditions and that responses to higher doses may be reduced. In one trial the use of rBST was associated with reduced DMI in cows exposed to heat stress[478]; this effect was not observed in other trials.[458,479] Collier and co-workers[480] reported that acclimation to heat stress is a two-step homeorrhetic process that occurs in an acute stage of changes in secretion rate of hormones and a chronic stage of receptor population adjustments in target tissues. The time frame of acclimation is weeks rather than days. Cows treated with rBST adapt to heat stress by increasing water intake, respired vapor, and skin vapor.[476–478] These adaptations require energy and divert cardiac output away from the udder. Several studies have shown that the milk response to rBST administration is lower (up to 55%) in cows exposed to high temperatures provided with shade as opposed to shade and an evaporative cooling system.[450,479] Several studies have shown that higher rectal temperatures may be experienced in rBST-treated cows under heat stress conditions.[450,458,465,477] Although milk production was increased, the response may likely have been depressed because of energy expense toward homeostatic thermoregulation. The lower responses to rBST observed in herds in hot climate conditions may be explained in part by the effect

of decreased DMI on IGF-I in plasma.[474] Dietary rations for heat stressed cows may need reformulation for higher nutrient density to offset the reduced DMI. No negative effects have been observed during rBST use under cold conditions.[481,482]

41.1.8.3

IMPACT OF SOMATOTROPIN ON REPRODUCTION

The aspect of rBST use most likely to result in involvement of the veterinarian is its effects on fertility. The positive effects of rBST on milk production can be accompanied by both positive and negative effects on reproduction. Although a study by De la Sota and colleagues[443] found that lactational status (lactating vs. nonlactating) had a greater effect on reproduction than the use of rBST, the following discussion is limited to the reproduction of lactating cows.

In general the negative effects of rBST on reproduction in lactating cows have been reported to be an increase in twinning rate and days open.[472,483,484] The increased twinning rate is likely due to better embryo survival, because ovulation rate does not appear to be increased in rBST-treated cows.[448,485] There is, however, reason to suspect an increased ovulation rate based on recent studies that reported that increased feed intake results in higher rates of steroid metabolism in the liver.[486,487] More rapid metabolism of estradiol can result in decreased negative feedback on follicle-stimulating hormone (FSH), allowing additional follicles to undergo changes necessary to proceed to ovulation.[487] The increase in days open could be attributable to a prolonged negative energy balance associated with the increased milk production. The magnitude of the increase in days open was estimated to be 5 days in a metaanalysis performed on data from 18 studies.[484] The relative risk of nonpregnancy in rBST-treated cows during the same period as control cows was 1.38 in a metaanalysis of nine studies.[484] One explanation for nonpregnancy can be that cows treated with rBST do not show outward signs of estrus with the same intensity as untreated cows,[444,488] and therefore accurate heat detection is hindered. Estrous detection rate decreased linearly with increasing dose of rBST[488] despite the finding that rBST treatment had no effect on incidence of cystic ovaries.[452,484,485,489]

A confounding factor in any evaluation of the effect of rBST on reproduction is the fact that rBST-treated cows maintain profitable milk production longer and therefore these cows can be rebred, if open, at longer DIM than untreated cows. The resultant pregnancies from these breedings late in lactation will increase the average days open for the herd. On the other hand, any additional pregnancies under rBST use as a result of longer breeding windows could be considered a positive effect of the use of rBST, because they would not be obtainable under the same management in untreated cows. The evidence that these two effects offset each other comes from a study that evaluated the effect of rBST use on culling in 32 herds, which showed no difference between culling rates (overall and culling because of reproductive factors) in herds that used rBST and control herds.[490] The potential negative effects of rBST on estrous behavior may favor the decision to use timed artificial insemination (TAI) programs, because TAI does not rely on estrous detection to breed the cow.

1384

1385

Positive effects of rBST on reproduction have been elucidated in recent studies that showed first-service pregnancy rate is increased in rBST-treated cows.[491–493] This effect is not independent of the timing of the last rBST injection.[444,491] The first-service pregnancy rate was increased in cows receiving rBST between 1 and 3 days before the first gonadotropin-releasing hormone (GnRH) injection of the Ovsynch program. In another study, pregnancy rates were increased in lactating, multiparous cows when a single dose of rBST was administered at time of insemination.[493] Some studies have found increased conception rates in cows treated

with lower doses of rBST as compared with cows treated with higher doses.[488,494] Furthermore, rBST has shown a positive effect on embryo transfer (ET) programs, both in the donor and the recipient animals.[448,495] When rBST was given at the initiation of the superovulation regimen in donor animals, two more transferable embryos were obtained—a net increase of 28% to 37%. The increased recovery of transferable embryos can be attributed to a direct effect of rBST on the superovulated ovary and an indirect effect of IGF-I. The effect on recipient animals when the donor cow was not treated was to increase pregnancy rates by 68%,[448] explained by better embryo survival, because GH and IFN-tau have added effects in inhibiting uterine $PGF_{2\alpha}$ production.[445] The effect of rBST on the fetus has shown some inconsistencies. In one study, calves born to rBST-treated cows had a gestation length 2 days shorter and weighed 2 kg less compared with contemporary controls,[454] whereas in another study they weighted 3 kg more than controls.[472] The effect could be dependent on energy balance (similar to the effects on milk production). In summary, rBST initially has positive effects on reproduction, but within weeks the metabolic consequence of increased milk production has a negative impact on reproduction. In herds not using rBST for increased milk production, the use of low doses of rBST could be beneficial for individual cow conception rates.

41.1.8.4 IMPACT OF SOMATOTROPIN ON HEALTH

41.1.8.4.1 Mastitis

Several studies have reported that rBST use was associated with an increase in clinical cases of mastitis.[422,484,489,496,497] In these studies no attempt was made to differentiate between contagious and environmental mastitis cases or the effect that increased milk production has on mastitis incidence. Studies on well managed farms where contagious mastitis was being controlled reported no effect of rBST on clinical mastitis.[498,499] SCC levels in milk from rBST-treated cows are not significantly different from those in untreated cows.[422,423,460,484] If rBST supplementation is used in cows with high SCC levels, the response in milk production is lower than if rBST is used in cows with lower SCC levels.[422] The incidence of clinical mastitis in rBST-treated cows has been reported to be similar to the mastitis incidence consistent with the genetic improvement of milk yield per cow.[497,500] White and colleagues[497] suggested that mastitis should be evaluated as incidence per unit of milk produced. Cows of a given production stratum reportedly had similar mastitis incidence whether they were treated with rBST or not.[497] A metaanalysis of 11 studies found an increase in clinical mastitis cases of approximately 19.4% in the rBST-treated cows, without controlling for the increase in milk production (11% to 15.6%).[484] To further complicate interpretation of the effect of rBST, the incidence of mastitis in mid and late lactation (31 to 150 DIM and 151 to 365 DIM) depends on the incidence early in lactation (0 to 30 DIM).[501] Therefore if mastitis incidence is not measured before treatment with rBST (according to label after 57 to 70 DIM), mastitis incidence during the treatment period should be interpreted with caution. No differences in culling rates as a result of mastitis were observed in a comparison of herds that used rBST and control herds (total of 64 herds in three studies).[489–490,498] Several trials were designed to assess the effect of rBST on experimentally induced mastitis with environmental bacteria (*Streptococcus uberis*[418,502] and *Escherichia coli*[503]). Clinical signs of mastitis, milk composition changes, and bacteria counts in milk were all reduced in rBST-treated cows. Therefore overall production losses during induced mastitis episodes were lower in rBST-treated cows than in control cows, indicating a positive effect of rBST on the immune response.[416–418]

41.1.8.4.2

Lameness

Preapproval trials for rBST were designed as either dose titration studies or clinical trials of the effect on milk production; the trials did not capture in-depth health information. A metaanalysis[484] of 18 preapproval studies that collected data on disease incidence reported negative effects of rBST on lameness and culling of adult cows (second or greater lactation). This study reported a risk ratio (RR) of 1.55 for clinical lameness and 1.36 for culling of older cows treated with rBST compared with control cows. Ruegg and colleagues,[490] however, showed no differences in culling rates (overall or because of lameness) between herds that used rBST and control herds. Another study showed that the higher risk of lameness occurred in the lactation after treatment with rBST but not during treatment.[452] In this study, however, the higher risk of lameness was attributed to management (tie-stall housing), because no changes could be found on histopathology preparations.

41.1.8.4.3

Metabolic Diseases

The effect of rBST on fat mobilization is a decrease in body condition score,[436,437,469] which in turn results in lower NEFA and BHB plasma levels and a lower incidence of postparturient metabolic diseases such as ketosis and milk fever (hypocalcemia) in the subsequent lactation.[452,469] One study within the previously reported metaanalysis[484] showed a fourfold reduction in the incidence of metabolic diseases (RR = 0.25) owing to the carryover effect in the lactation after rBST treatment. Data on the incidence of other diseases commonly reported in dairy cattle were either insufficient or not collected in a consistent manner to allow objective evaluation.

41.1.8.4.4

Toxicity

Studies on the potential toxicity of high doses of rBST in dairy cattle,[457,470,504] even when administered for long periods (six times the approved dose over two consecutive lactations),[470] have shown no negative effects. The highest tested dose was 60 times the approved dose of rBST administered weekly for 4 weeks.[504] Apparent negative health effects were also not observed in the many experimental studies of rBST use.* Although cows treated with rBST tend to have lower hematocrit (packed cell volume) and hemoglobin values,[457,504,506] both remain within the normal range for dairy cattle. 1385

41.1.8.5

HUMAN AND FOOD SAFETY

The safety of milk and meat products from rBST-treated cows is based on three tiers of biologic protection:

1 Bovine GH has no activity in humans, even if injected.

2 GH and IGF-I have no oral activity and are inactivated in the gastrointestinal tract.

3 GH and IGF-I concentration in milk and meat are essentially unchanged with rBST use.

Bovine GH has been studied in depth as a potential source for therapeutic GH for hypophysectomized human patients.[507] Bovine and human GH differ in 69 of 191 amino acids in their sequences (approximately 36%).[395] The difference in their structure and the much lower binding affinity of bovine GH for human GH receptors (up to 3000 times)[508–510] renders bovine GH inactive in humans. Therefore contact with rBST should have no effect on people, even if injected.

The safety of consuming animal products (meat and milk) from cows treated with rBST has been extensively studied. Milk naturally contains GH and IGF-I; concentrations of both are highest during the first days of lactation[407,511–513] when milk cannot be marketed for human consumption (colostrum),[514] and decrease as lactation progresses. GH levels in milk were similar in cows treated with rBST and untreated cows and decreased by 85% to 90% when milk was heat-treated.[515] IGF-I concentration in cow milk has been reported in colostrum to be 233.8 ± 26.9 ng/mL, decreasing to 8.8 ± 1.5 ng/mL at 2 weeks postpartum.[516] Physiologic concentrations of IGF-I in cow milk vary widely according to parity and stage of lactation, ranging between 1.27 and 8.10 ng/mL in bulk tank samples.[398,511] Although treatment with rBST slightly elevates IGF-I concentration in milk,[398,519] levels remain within physiologic range. Therefore, it is not possible to determine whether cows have been treated with rBST based on measurement of IGF-I and GH in milk.[519,520] The only reliable method to determine whether cows have been treated with rBST is the measurement of GH levels in blood several times over the 14-day injection interval.[519,520]

Levels of IGF-I in milk tended to be higher after pasteurization than in raw milk (8.2 ± 0.35 ng/mL vs. 5.6 ± 0.56 ng/mL),[511] presumably because IGF-I is released from its binding proteins. Infant formulas, which require higher pasteurization temperatures, had almost undetectable levels of IGF-I (0.7 ng/mL).[511] Muscle of cows treated with rBST had levels of GH and IGF-I similar to those of untreated cows.[521] Like most ingested proteins, rBST and IGF-I are degraded by the digestive enzymes of the gastrointestinal tract, rendering them biologically inactive.[398,515,521,522] Therefore rBST has been shown to be safe and has been approved to be used with zero days withholding of meat and milk for human consumption.[400]

Table 41-11 Relative Magnitude of Increased Milk Production Obtained by the Use of Different Technologies in Dairy Cows*

Technology and Reference Category	Cost	Effect on Milk Production: Cow	Effect on Milk Production: Offspring	Effect on Milk Production: kg/year	Reference
AI vs. natural service	$ Semen · S/C · % female calves · (1 – mortality)†	—	✓	367–441 730	523524
ET vs. AI	$ Embryo · PR · % females · (1 – mortality)†	—	✓	‡372	525
3× milking vs. 2× milking	Labor + energy + milking hygiene products§	✓	✓	1,417 1,573	526527
Cooling in hot weather vs. not cooling	Installation + maintenance + increased feed intake	✓	✓	769	526
rBST vs. none	$ rBST + labor + increased feed intake + facilities (if not in place) + cost of TAI program (if not in place)	✓	✓	1,298 1,301	526527

AI, Artificial insemination; *ET,* embryo transfer; *PR,* pregnancy rate; *rBST,* recombinant bovine somatotropin; *S/C,* services/conception; *TAI,* timed artificial insemination.

* The reference category for each technology is provided. When comparing offspring, the reference category was the offspring of cows not exposed to the technology. Note that the effect on the cows is immediate, whereas the effect on the offspring will start approximately 3 years later (9 months of pregnancy plus 2 years until calving). The effect on offspring is restricted to female offspring that survive to freshening: less than 50% of all offspring.

† Mortality of female calves from birth until they calve (2 years of age).

‡ Estimated genetic gain.

41.1.8.6

RECOMMENDATIONS FOR USE OF RECOMBINANT BOVINE SOMATOTROPIN

As described previously, there is overwhelming evidence that rBST has a strong galactopoietic effect and will increase average herd production when used according to label directions. When compared with other technologies developed over time to increase milk production in the dairy industry, the use of rBST and 3× milking are the two methods that can make an immediate and significant impact on herd milk production (Table 41-11). Genetic methods[523–525] of improving milk production do not affect the cow on which they are applied. They will improve milk production in the female offspring, once they are mature (less than 50% of all offspring). In contrast, methods such as cooling cows during hot weather,[526] milking cows 3 times per

day (3×) as opposed to twice per day (2×),[526,527] and using rBST improve milk production directly in the cows and their mature offspring. In fact, use of rBST can further increase milk production in herds that are already benefiting from higher production resulting from 3× milking.[526,527]

Responses to rBST are highly variable among herds; therefore individual dairymen need to determine whether the rBST response justifies the cost. Basic costs that need to be taken into account include the cost of the product plus additional labor and feed costs. Another expense to consider is the cost of implementing a TAI program (labor and drugs) to offset the negative effect of rBST on estrous expression and pregnancy rate, although TAI may have benefits independent of rBST use. Not all studies have found rBST to be significantly profitable.[528,529] The use of rBST has minimum facilities and management requirements such as a reliable restraint method (automatic headlocks, stanchions, or tie-stalls), visual identification of all cows (eartags or freeze brands), herd management computer software, and the ability to deliver a consistent, high-quality ration, preferably a TMR.

1386

1387

The labeled use of rBST in the United States is 500 mg administered SC every 14 days starting at 57 to 70 DIM. Individual cow identification, restraint, and computerized records are important to ensure that cows are treated with rBST every 14 days. Because all cows will not show a significant improvement in milk production, individual responses may be monitored so that treatment can be limited to responsive cows. Herds that intend to profit from rBST must provide the husbandry needed to maximize DMI in the cows. Feed quality, palatability, and availability are major determinants of DMI, along with water availability, cow comfort, and heat abatement, and thus will influence success of rBST usage. Feed consistency can best be guaranteed by a large high-quality forage base so that minimal ration adjustments are necessary. When cows treated with rBST become sick, they should remain on rBST because of the enhanced response to infection and endotoxemia.[416–420] The sick cow diet should not significantly drop in energy, or the effect of rBST (through IGF-I) on milk production and immune function will likely be reduced. Because the response to rBST in cows is greater in late lactation than in early lactation, both in kilograms and in percentage improvement, delaying the start of rBST use until later in lactation could further benefit the cows, allowing additional pregnancies to occur without a large reduction in overall response in milk production.

Potential uses of rBST, other than blanket herd use for improved milk production, include treating repeat breeder cows for improved fertility, improving fertility in embryo transfer programs (in both donor and recipient cows),[448,495] helping fat cows achieve target BCS,[422,435] preventing ketosis in the subsequent postpartum period,[452,469] and reducing or delaying culling in cows that abort and in “do not breed” cows. Potential uses of rBST in the future (if approved) may include production enhancement of cows after lactation induction,[530] integration into programs with no dry periods,[407,531,532] and use on young stock to induce more rapid growth of lean body mass[475,533] and in nutrient management programs to reduce manure, urine, and methane production per pound of milk produced.[534]

42 Chapter 42 Diseases of Muscles

Consulting Editors

Stephanie J. Valberg

42.1 EXAMINATION OF THE MUSCULAR SYSTEM

STEPHANIE J. VALBERG

Clinical evaluation of the muscular system requires a systematic and routine method of examination. Often a veterinarian is asked to examine an animal with a history of a relatively nonspecific disease process that may be the result of muscular dysfunction. Animals with electrolyte imbalances, pleuritis, colic, chronic wasting diseases, poor performance, and a number of lameness problems may initially have signs similar to those seen with some forms of muscular dysfunction.

A thorough history of the animal or animals involved is an integral part of characterizing the muscle disorder, particularly because many disorders are intermittent in nature and triggered by certain environmental stimuli. A careful description of the animal's muscle tone, muscle mass, gait, degree of pain, exercise intolerance, and weakness while experiencing clinical signs should be obtained. In addition, the duration of illness, intermittency of clinical signs, factors precipitating clinical signs, exercise schedule, diet, current medications, vaccination history, and number of other animals affected and their familial relationships should all be recorded before the muscular system is examined.

42.2 PHYSICAL EXAMINATION

Initially the animal can be observed from all aspects at a distance while the horse is standing with forelimbs and hindlimbs exactly square. The examiner should observe the size, shape, and symmetry of all muscle groups and look for muscle fasciculations. This observation helps provide impressions about tropic changes, alterations in symmetry of particular muscle groups, and spontaneous muscle activity.

The animal can then be walked, trotted, or driven and evaluated for gait abnormalities. The symmetry of the gait and evidence of lameness, weakness, stiffness, and pain associated with movement can be noted. Gait abnormalities may result from pain, muscle weakness, muscle cramping, spasticity, decreased range of joint motion, dysfunction of motor neurons, and ataxia. A number of muscular diseases may result in one or many of these clinical manifestations. For example, horses with exertional rhabdomyolysis (ER) may be lame or stiff and demonstrate significant pain when encouraged to move. In contrast, horses with fibrotic myopathy may demonstrate a characteristic exaggerated gait abnormality with little evidence of pain.

After initial visual evaluation, muscles should be palpated. It is suggested that as many muscle groups as possible be palpated to obtain an overall impression of muscle tone, consistency, sensitivity, swelling, atrophy, and heat. Firm, deep palpation of the lumbar, gluteal, and semimembranosus and semitendinosus muscles may reveal pain, cramps, or fibrosis. Comparisons between muscle groups and areas of the animal can then be made to identify atrophy or swelling. Some animals are tense and demonstrate apparent evidence of myalgia when palpation is first performed. However, given time and patience, many of these animals relax, and muscles or muscle groups that at first examination appeared to be very sensitive or hypertonic may in reality be normal. By this stage it can often be determined whether individual muscles, muscle groups, a limb or limbs, or the whole body musculature is

involved. The symmetry or absence of symmetry of affected muscles or muscle groups is also important for potential evaluation of muscle disorders. Horses should stand perfectly square when bilateral muscle groups are compared.

Fine muscle tremors can be palpated and auscultated with a stethoscope. Concurrent signs of anxiety or pain should be noted and the animal reevaluated in calm surroundings if necessary. In animals with spontaneous muscle activity, muscle groups should also be percussed with a percussion hammer. The triceps, pectoral, gluteal, and semitendinosus muscles are often easily accessed for percussion. A positive percussion sign occurs when the soft tissue overlying the muscle becomes dimpled for several seconds (percussion myotonia) (Fig. 42-1). This occurs as the result of abnormal mechanical irritability and sustained contraction of the percussed fibers. Running a blunt instrument such as artery forceps, a needle cap, or a pen over the lumbar and gluteal muscles should elicit extension (swayback) followed by flexion (hogback) in healthy animals. Guarding against movement may reflect abnormalities in the pelvic or thoracolumbar muscles or pain associated with the thoracolumbar spine or sacroiliac joints.

If there is evidence of weakness, differentiation between myasthenia of muscular and neurologic origin is ideal. This requires a detailed neurologic examination. However, this can often be extremely difficult because a close junctional relationship exists between the nervous and muscular systems. In general, muscular weakness is not associated with ataxia unless it is extremely severe. Weakness is often manifested by muscle fasciculations, knuckling at the walk, frequent recumbency with difficulty rising, and shifting of weight because of an inability to fix the stifles.

If the primary abnormality identified is related to exertion, a lameness evaluation including flexion tests is often indicated as part of evaluation of the muscular system. Muscle pain may be secondary to changes in movement caused by lower limb lameness. The horse should be observed at a walk or trot for any gait abnormalities and in some cases longed for 15 minutes or ridden until clinical signs are elicited.

42.3 CLINICAL PATHOLOGY

42.3.1 Serum Enzyme Activities and Myoglobin Concentrations

Serum enzyme activities can be extremely useful in determining whether muscle cell necrosis is a predominant feature of a suspected muscle disease. Under normal conditions the serum activities of the enzymes used to assess muscle damage are low. However, leakage of the enzymes from myocytes into the bloodstream may occur if the cell membrane is disrupted through muscle cell necrosis or if the permeability of the cell membrane is increased. A number of other factors may influence the activities of enzymes within the circulation. These include rate of enzyme production, alternative sources of the enzyme, rate of enzyme excretion and degradation, and alterations to the pathways involved in enzyme removal or inactivation.[1]

Three enzymes are used routinely in the assessment of muscular diseases in large animals: creatine kinase (CK), aspartate aminotransferase (AST), and lactate dehydrogenase (LDH). Carbonic anhydrase III and serum myoglobin have also been suggested as markers of equine muscle necrosis.[2,3]

Serum CK offers remarkable sensitivity as an indicator of myonecrosis. This enzyme is found predominantly in skeletal and heart muscle. It is intimately involved in energy production within the cell, is highly concentrated within the cytoplasm, and is readily liberated into the extracellular fluid when the muscle cell membrane is disrupted.[1,4]

Changes in CK can be used as an indicator of muscle dysfunction in relation to a variety of insults. Serum activity of this enzyme increases within hours in response to a muscle insult. Limited elevations in CK may accompany training, transport, and strenuous exercise. Elevations of CK to 400 or 500 IU/L may occur when training commences or in response to moderate exercise.[5] Extremely fatiguing exercise (e.g., endurance rides or the cross-country phase of a 3-day event) may result in CK levels being increased to more than 1000 IU/L but usually less than 8000 IU/L. These elevations usually are not reflective of an extensive myopathy, and serum levels of CK rapidly return to baseline (i.e., less than 250 IU/L in 24 to 48 hours). Recumbent animals also may have slightly elevated CK levels that are usually less than 3000 IU/L. In contrast, more substantial elevations (from several thousand to hundreds of thousands of international units per liter) in the activity of this enzyme may occur with rhabdomyolysis.[1,4]

Several different isoforms of CK exist. Electrophoretic migration in a field of direct current results in the separation of three bands: MM, MB, and BB. Skeletal muscle is rich in the MM isoform, cardiac muscle is rich in the MB isoform, and neural tissue contains the BB isoform. Rhabdomyolysis results in a proportionately greater increase in the MM isoform than the MB isoform.[6]

Serum AST, previously known as *serum glutamic-oxaloacetic transaminase* (SGOT), also has been used as an aid to diagnose muscular necrosis in large animals.[1,4] The enzyme has high activity in skeletal and cardiac muscle and also in liver, red blood cells (RBCs), and other tissues. Elevations in AST are not specific for myonecrosis, and increases can be the result of hemolysis or muscle, liver, or other organ damage. Alterations in AST activity are an integral component of many serum biochemical “profiles.”

AST activity rises more slowly in response to myonecrosis than does CK, often peaking 24 hours after the insult, and the half-life of AST is much longer than that of CK.[7] By comparing serial activities of CK and AST

in animals with suspected myopathy, information concerning the progression of myonecrosis may be derived. Elevations in CK and AST reflect relatively recent or active myonecrosis; if CK remains persistently elevated, myonecrosis is likely ongoing; and elevated AST activities accompanied by decreasing or normal CK activities indicate that myonecrosis is not continuing.[1,4]

Elevations in serum LDH activity occur because of damage to various organs within the body. LDH is composed of muscle (M) and heart (H) subunits. The enzyme is a tetramer made up of combinations of the M and H subunits, with five isoenzyme forms. Although the distribution of isoforms is genetically determined, electrophoretic separation suggests that the M_4 (LDH_5) and M_3H (LDH_4) isoforms are found predominantly in skeletal muscle. Elevations in LDH may be detected in horses with rhabdomyolysis, myocardial necrosis, and/or hepatic necrosis. Therefore in the presence of elevations of total LDH activity, electrophoretic separation of LDH into its isoenzyme forms may be necessary if definitive evidence of skeletal myonecrosis is to be obtained.[1]

Whenever possible, consideration should be given to providing optimum conditions for collection, handling, and storing of serum or plasma samples for subsequent determination of enzyme activities. CK is labile when stored at room temperature. Activity of CK in serum samples stored for 24 hours at room temperature falls to approximately 25% of activity at the time of collection. When kept at between 0° C and 4° C (32° F and 39° F), only 32% to 65% of the activity remains after 24 hours. In contrast, freezing of samples allows maintenance of CK activities for several days. However, after 8 days of frozen storage, activity falls to approximately 25% of the original value. Despite this apparent rapid decline in the serum activity of CK, CK determination from samples stored under less than ideal conditions may still reveal useful information.[1] This is particularly true in cases in which large elevations in CK activity occur in response to myonecrosis. In these animals, CK activity may rise to a peak value of hundreds of thousands of international units per liter. Even if CK activity does fall significantly in storage, it remains elevated within the sample for several days, potentially providing evidence of myonecrosis. The enzymes AST and LDH are much more stable under a variety of storage conditions, with less than 25% of the activities of both enzymes being lost over an 8-day period in samples stored at room temperature, 0° C to 4° C (32° F to 39° F), or frozen. Freezing samples for LDH isoenzyme determination alters the configuration of the isoforms, making interpretation of the results unreliable. However, total LDH activity remains unaffected.[1]

Therefore under ideal conditions samples for subsequent determination of CK, AST, and/or LDH should be collected into a glass (serum) or heparinized tube. The serum or plasma should be harvested as soon as possible, because anoxia and lysis of RBCs allows the liberation of AST and LDH. If possible, serum and plasma samples should be transported rapidly to the laboratory. Otherwise they should be kept chilled (4° C [39° F]) if analysis is to occur within 24 hours. When determination of CK activity is required and a delay of more than 12 hours is anticipated, freezing of the samples is desirable.[1]

1389

1390

Elevations in plasma and serum myoglobin concentrations provide an indication of recent muscle damage. Myoglobin is a small protein that leaks into plasma immediately after muscle damage and is rapidly cleared in the urine by the kidney. It is particularly useful for determining exercise-associated muscle damage, because peak concentrations are reached shortly after exercise compared with 4 to 6 hours later for CK.[8,9] Unfortunately, few laboratories can routinely measure myoglobin. Normal concentrations in resting horses have been determined by nephelometry (range 0 to 9 µg/L),[3] with measured concentrations with rhabdomyolysis ranging from 10,000 to 800,000 µg/L.[10]

42.3.2 Urinalysis

Urine can be obtained free catch from horses placed in stalls with fresh bedding or via catheterization. The most accurate reflection of fractional excretion (FE) of electrolytes is obtained from samples obtained without tranquilization. Urinalysis is particularly important in horses with myoglobinuria, elevations in creatinine, or suspected electrolyte imbalances. Urine specific gravity, protein content, white blood cell (WBC) count, RBC count, and evaluation of cast formation should be performed to assess the potential for concurrent renal disease. A positive Hemastix test (orthotoluidine) result in the absence of hemolysis or RBCs in urine is highly suggestive of myoglobinuria. Further differentiation of myoglobin from hemoglobin is sometimes warranted, and where available electrophoresis, nephelometry, or spectroscopy may be used. Spectroscopy does not always reliably distinguish between myoglobin and hemoglobin.

Determination of electrolyte, mineral, and creatinine concentrations in urine and blood has been used to determine electrolyte balance in horses with muscle cramping or ER.[11] Problems often encountered however, are the large fluctuations in daily electrolyte excretion that occur in the same horse and among horses, the interference of high urinary potassium concentrations with measures of sodium concentrations when an ion-specific electrode is used, and the presence of calcium crystals in equine urine, which artifactually decrease the calcium and magnesium measured if urine samples are not acidified.[12] Renal fractional excretion (FE) can be calculated using the following formula:

$$FE_X = \frac{S_{Cr} \times U_X \times 100}{U_{Cr} \times S_X}$$

where *U* is urine, *S* is serum, *x* is measured electrolyte, and *Cr* is creatinine.

If urine calcium is to be determined, acidification of urine to dissolve all calcium oxalate crystals is recommended to provide exact calcium excretion. Determination of potassium, chloride, magnesium, and phosphorus concentrations can be performed using ion-specific electrodes or inductively coupled plasma atomic absorption.

Normal values for FE of electrolytes depend on a horse's diet. Normal values (%) for horses consuming grass, hay, and a sweet feed mix with available salt are FE_{Na} 0.04 to 0.08, FE_K 35 to 80, FE_{Cl} 0.4 to 1.2, FE_{Ca} 5.3 to 14.5, FE_P 0.05 to 4.1, and FE_{Mg} 14.2 to 21.4.[12,13]

42.3.3 Exercise Testing

Evaluation of muscle disorders that are precipitated by exercise may require an exercise challenge test. An exercise test should not be used in horses with overt signs of rhabdomyolysis but rather to determine if horses not currently showing clinical signs are prone to ER. The goal is to induce subclinical elevations in serum CK activity. Abnormal increases in CK are more likely to occur if slow trotting is performed rather than strenuous exercise.[9] Often 15 minutes of exercise at a walk and trot in unfit horses or at a constant slow trot in fit horses will elucidate subclinical elevations on CK. If signs of stiffness develop before this, exercise should be concluded. CK activities in blood samples taken immediately after exercise do not reflect the amount of exercise-induced muscle damage. For best results, blood samples for CK activity should be taken before and 4 to 6 hours after exercise. In healthy horses, 15 to 30 minutes of light exercise rarely causes more than a threefold increase in CK activity.[14,15] Elevations greater than fivefold are indicative of ER. Standardized

treadmill exercise testing can also be used to evaluate muscle responses and measure metabolic responses to exercise.

42.3.4 Electromyography

Electrodiagnostic studies detect spontaneous or evoked potentials of neurogenic or myogenic origin using electrodes positioned in the muscle. Electromyography (EMG) is particularly useful to evaluate large animals with altered muscle tone. EMG of normal skeletal muscle shows a brief burst of electrical activity when the needle is inserted (insertional activity) in muscle and then quiescence, unless motor units are recruited (motor unit action potentials) or the needle is very close to a motor end plate (miniature end plate potentials). Normal muscle shows little spontaneous electrical activity unless the muscles contract or the horse moves. Horses with abnormalities in the electrical conduction system of muscle, or denervation of motor units, show abnormal spontaneous electrical activity in the form of fibrillation potentials, positive sharp waves, myotonic discharges, or complex repetitive discharges.[16–19] Fibrillation potentials and positive sharp waves represent spontaneous firing of muscle fibers. Myotonic discharges are bursts of complex high-frequency potentials, whereas complex repetitive discharges are similar but have fixed amplitude and frequency. They both represent simultaneous firing of groups of muscle fibers. Motor unit action potentials can be evaluated to assess their amplitude, duration, phase, and number of phases. Myopathic changes include a decrease in duration and amplitude of motor unit action potentials.[17,19] More information about the motor unit could be provided by nerve conduction velocities (NCVs); however, the inaccessibility of motor nerves makes measurement difficult in large animals. Both EMG and NCVs are used to classify the primary disease as neuropathic or myopathic, to determine the distribution of the disease, and to provide insight into the pathophysiologic mechanisms of the disease.[16,20] Equipment costs are relatively high, and expertise is required in operation and interpretation of results. Readers are advised to consult Chapter 35 before considering the use of EMG.

42.3.5 Nuclear Scintigraphy

Nuclear scintigraphy is useful for identification of some forms of muscle damage, particularly an area of deep muscle damage that was not suspected based on clinical examination.[21] Technetium-99 m methylene diphosphonate (MDP) is taken up in some damaged muscle in the horse and is best seen in bone phase images (e.g., 3 hours after injection). Scintigraphy has been used in horses with a history of poor performance, with or without stiffness after exercise, to confirm a diagnosis of equine rhabdomyolysis.[22] The mechanism of MDP binding is unknown, but the release of large amounts of calcium from damaged muscle or the exposure of calcium binding sites on protein macromolecules in the damaged muscle may be responsible. Scintigraphy may be helpful in some cases involving focal damage to either proximal forelimb or hindlimb muscles.[21]

1390
1391

42.3.6 Ultrasonography

Diagnostic ultrasonography is potentially very useful for identification of muscle trauma, crepitus, fibrosis, and atrophy. Muscles have a rather typical striated echogenic pattern, but this varies according to the muscle group, and careful comparisons must be made between similar sites in contralateral limbs, in both transverse and longitudinal images.[21] The appearance of muscle is also sensitive to the way the animal is standing and whether the muscle is under tension, so it is important that the animal be standing squarely and bearing weight evenly. Muscle fascia appears as well-defined relatively echodense bands.[21] Care must be taken in identifying large vessels and artifacts created by them.

In an acute injury, muscle fiber disruption is seen as relatively hypoechoic areas within muscle, with loss of the normal muscle fiber striation. The jagged edge of the margin of the torn muscle may be increased in echogenicity.[21] Tears in the muscle fascia may be identified. The defect in muscle may be filled by loculated hematoma that is hypoechoic. As the muscle repairs, it becomes progressively more echogenic. Relatively hyperechoic regions may be a result of increased connective tissue or loss of muscle cell mass. Hyperechoic shadowing artifacts usually represent mineralization or gas pockets.[21]

42.3.7 Muscle Biopsy

Examination of muscle fibers, neuromuscular junctions, nerve branches, connective tissue, and blood vessels within a biopsy sample can provide additional information necessary to fully characterize a neuromuscular disorder.[23–25] Routine light and electron microscopic examinations, combined with histochemical evaluations, may provide insights into the particular manifestations of neuromuscular diseases and their rate of progression. A number of basic pathologic responses of muscle can be identified in paraffin-fixed sections. These include inflammatory infiltrates, muscle fiber necrosis, muscle fiber regeneration, increased number of central nuclei, variations in muscle fiber sizes and fiber shapes, vacuolar change, and proliferation of connective tissue. However, many pathologic alterations cannot be detected in formalin-fixed tissue but can readily be seen in histochemical stains of fresh-frozen biopsy samples.[23–25] These include muscle fiber types and their pattern of distribution, differentiation of neurogenic atrophy from disuse atrophy or a primary myopathy, characterization of vacuolar storage material, characterization of inclusion bodies, assessment of mitochondrial density, and additional clues that may allow identification of a specific disorder or category of muscle disorders. Furthermore, formalin fixation results in artifactual cracking, fiber shrinkage, and leakage of substrates such as glycogen, which can affect proper interpretation of muscle pathology.

When collection of muscle biopsies is under consideration, some general guidelines apply. Preferably samples should be collected from what is considered abnormal or diseased muscle. A 6-mm outer diameter* percutaneous needle biopsy technique can be used to obtain small muscle samples through a ¼-inch skin incision using a local anesthetic subcutaneously. If this technique is used, enough muscle should be obtained to form a ½-inch square sample at a minimum. These samples do not, however, tolerate shipment to an outside laboratory. The optimum biopsy sample for shipment of histopathology tissues to a laboratory is collected using surgical or open techniques, performed under local anesthesia. Care must be exercised to infiltrate only the subcutaneous tissues, not the muscle, with the anesthetic agent. The objective is to obtain approximately a ½-inch cube of tissue; hence a suitably long skin incision is required. Two parallel incisions ½ inch apart should be made longitudinal to the muscle fibers with a scalpel. The muscle should be handled only in one corner, using forceps, and crushing should be avoided. The muscle sample is then excised by cross-secting incisions ½ inch apart, and the tissue is fixed appropriately. Routine histopathology samples can be placed in formalin; fresh samples can be placed in a watertight hard container after being wrapped in gauze moistened with saline, and shipped chilled to laboratories for freezing. On arrival at specialized laboratories, fresh samples for histochemical analysis are fixed in isopentane (methylbutane) chilled in liquid nitrogen to ensure rapid freezing and minimization of freeze artifact. Samples that potentially may be used for biochemical analysis should be immediately frozen in liquid nitrogen. Other routine histopathologic techniques may also be of diagnostic value. A special fixative may be required if such practices are to be undertaken. Samples for electron microscopy (EM) require appropriate fixation in glutaraldehyde preparations. Ideally, thin sections of muscle for EM should be clamped in vivo to maintain fibers at a resting length before they are excised. However, if pathology other than the alignment of thick and thin myofilaments is to be investigated, small muscle pieces can be excised and placed directly in appropriate EM fixative.

Responses of strips of fresh muscle to stimuli such as caffeine, halothane, and a variety of other agents can also be ascertained by specialized laboratories, but these are not routine diagnostic procedures.[26–28]

* Jørgen Kruuse, Marslev, Denmark.

42.4 CLASSIFICATION OF MUSCLE DISORDERS

STEPHANIE J. VALBERG

A muscle disorder is usually suspected in large animals because of (1) increased, decreased, or abnormal muscle contractions, (2) focal or generalized muscle necrosis (rhabdomyolysis), (3) muscle atrophy, or (4) exercise intolerance not associated with respiratory, cardiovascular, or skeletal causes.

42.4.1 ALTERED MUSCLE TONE

Increased muscle tone may be neural in origin. For example, tetanus and strychnine poisoning increase muscle tone as a result of suppressed inhibition of upper motor neurons by interneurons. Increased motor neuron firing also occurs during seizures, with electrolyte imbalances, and with equine ear tick infestation. Visual, tactile, or auditory stimuli often precipitate painful sustained motor unit activity. Other probable neural disorders that intermittently increase muscle tone include periodic spasticity and spastic paresis in cattle, stiff horse syndrome, and shivers in draft and warmblood horses.

1391

1392

Increased muscle tone can also result from myopathic disorders. Persistently enhanced muscle tone may occur because of muscle contractures, which are characterized by fixation of myofilaments in a persistently shortened position without neural input.[29] Contractures are usually extremely painful and associated with rhabdomyolysis. Contractures occur with malignant hyperthermia (MH) and some forms of exertional myopathy. Intermittent, abnormal muscle contractions without rhabdomyolysis occur when sarcolemmal ion channels within the muscle cell membrane are dysfunctional.[30,31] Caprine myotonia congenita and equine hyperkalemic periodic paralysis (HYPP) are examples of diseases caused by sarcolemmal ion channel dysfunction.

Moderate weakness in horses may be caused by central spinal cord disorders. More profound weakness may arise from neuropathies affecting motor neurons (equine motor neuron disease, hypocalcemia), decreased neural input at motor end plates (botulism), marked muscle atrophy or rhabdomyolysis of postural muscles, or severe electrolyte imbalances (hypokalemia). The few operative motor units fatigue easily, resulting in muscle fasciculations, shifting of weight, low head posture, difficulty prehending grain, long periods of recumbency, and difficulty rising.

42.4.2 MUSCLE ATROPHY

Atrophy is defined as a reduction in muscle size, specifically a reduction in muscle fiber diameter or cross-sectional area. Atrophy may occur in response to a variety of stimuli. Denervation removes the normal low-level tonic neural stimulus that is necessary to maintain muscle fiber mass. Complete denervation of a muscle results in more than a 50% loss of muscle mass within a 2- to 3-week period.[23,32] A good example of this is “sweeney” in horses, in which the suprascapular nerve is damaged and muscles over the scapula atrophy. Other denervating conditions such as equine motor neuron disease show a slower progression of gross muscle atrophy. Electromyographic abnormalities after denervation are apparent within 5 days, and it may take 3

weeks for maximal changes to develop. Increased insertional activity, positive sharp waves, and bizarre high-frequency discharges and fibrillation potentials are seen in denervated muscle.[19] Pyknotic nuclear clumps and small angular slow-twitch type 1 and fast-twitch type 2 fibers with concave sides are characteristic of neurogenic atrophy in muscle biopsies. In some cases hypertrophy of remaining motor units may occur in neurogenic atrophy, and renervation is indicated by target fibers and fiber type grouping.

Muscle atrophy also may be caused by disuse, malnutrition, cachexia, corticosteroid excess, and immune-mediated myositis. Skeletal muscle is a plastic tissue, with approximately 1% to 5% of the contractile mass undergoing remodeling on a daily basis. If a negative nitrogen balance occurs, net protein withdrawal from the skeletal muscle mass begins within 48 to 72 hours. This type of atrophy is distinguished from neurogenic atrophy by a slower progression of atrophy, normal electromyographic findings, and muscle biopsies that are characterized by exclusive atrophy of type 2 muscle fibers. The overall response of skeletal muscle is to maintain essential postural muscle groups, whereas less essential groups undergo significant reduction in muscle mass. With malnutrition, 30% to 50% of the muscle mass may be lost in the first 1 to 2 months.[32] Rapid atrophy is characteristic of immune-mediated myopathies in quarter horse—related breeds, which can result in the loss of 30% of muscle mass within 48 hours because of necrosis and atrophy of myofibers.[33]

42.4.3 MUSCLE NECROSIS

Muscle necrosis (rhabdomyolysis), as evidenced by elevations in serum CK, LDH, and AST, can be focal or generalized. Many infectious, toxic, nutritional, ischemic, and idiopathic factors result in muscle fiber necrosis. When attempting to identify a cause, it is helpful to characterize rhabdomyolysis in horses as associated with exercise or not exercise-associated. Specific causes of exertional and nonexertional rhabdomyolysis are listed in Box 42-1

Necrosis represents injury to organelles within a muscle fiber or within a segment of that fiber. Many myopathies associated with generalized rhabdomyolysis interrupt normal muscle metabolism, and cell death results from an inability to maintain homeostasis within the myofiber. Although various external or internal insults may cause rhabdomyolysis, they often share a final common pathway leading to cell death.[34] Under normal conditions, considerable energy is expended by muscle cells to pump the calcium that accumulates in the sarcoplasm during contraction into the sarcoplasmic reticulum. If cell membrane function is disrupted or if the energy pathways that generate adenosine triphosphate for the calcium pump are impaired, excessive calcium may accumulate in the sarcoplasm. Although some calcium can be sequestered by the mitochondria, eventually mitochondria become overloaded and oxidative metabolism ceases; oxygen free radicals are generated; phospholipases are activated, inducing the arachidonic cascade; calcium-dependent proteases are stimulated, and complement is activated. The contractile proteins within a necrotic segment are destroyed and appear homogenized with no evidence of cross-striations, and mitochondrial and sarcolemmal membranes appear disrupted. When necrosis occurs as a result of internal disruption of muscle homeostasis, the basement membrane of the cell is left intact. Macrophage infiltration and phagocytosis of necrotic debris usually occur within 16 to 48 hours of the muscle injury. Satellite cells migrate along the remaining basement membrane and form regenerative myotubes within 3 to 4 days of injury, with mature muscle fibers developing within a month of the original damage.[23]

42.4.3.1.2.4 Chronic Causes

Polysaccharide storage myopathy

Recurrent exertional rhabdomyolysis

Chronic exertional rhabdomyolysis (unknown causes)

Muscle ischemia occurs commonly with acute trauma, the compartment syndrome in recumbent animals, downer syndrome, and vascular occlusion. Compartment syndrome often involves the triceps muscle or extensors of the hindlimb, because they are often compressed in down animals or during anesthesia. Hypotension during surgery contributes to the development of this syndrome. Acute muscle infarction may occur with purpura hemorrhagica or disseminated intravascular coagulation, and on postmortem examination characteristic well-demarcated areas of hemorrhagic necrosis are evident. Clinically, acute infarctions are an extremely painful condition that may resemble colic. Chronic occlusive diseases, such as iliac thrombosis, often allow collateral circulation to develop, thereby avoiding acute signs of ischemia at rest. Although muscle has an impressive ability to regenerate, if a disease process is severe enough to disrupt the basement membrane, muscle may be replaced by connective tissue and fat. This occurs most frequently after trauma such as tearing of the semimembranosus or tendinosus in horses (fibrotic myopathy).

42.5 DISORDERS OF MUSCLE TONE

42.5.1 MYOTONIC DISORDERS

STEPHANIE J. VALBERG

Myotonic muscle disorders represent a heterogeneous group of diseases that share the feature of delayed relaxation of muscle after mechanical stimulation or voluntary contraction. Abnormal muscle membrane excitability appears to be the shared abnormality among myotonic disorders. The nondystrophic myotonias in large animals include myotonia congenita in horses and goats and equine HYPP.[35] Sarcolemmal ion channel dysfunction causes these nondystrophic myotonias. Dystrophic myotonia, a progressive disease that may also be associated with abnormalities in other body systems, has been reported in horses.[36,37] In addition, it has been noted that some horses with ear tick infestations develop percussion myotonia and painful muscle cramps.[38]

A condition that demonstrates myotonic-like signs in cattle is spastic paresis[39,40] or “Elso heel.” Commonly calves 2 to 7 months of age are affected and have an extremely straight angle to the hock and stifle. Signs reflect a decreased ability or inability to flex the hock because of continuous tension on the gastrocnemius muscle when standing. Involvement may be unilateral or bilateral. The Holstein-Friesian breed is most commonly affected, although other breeds have been found to have the disorder.[39–42] Spastic paresis may have a distinct familial pattern, but environmental exposure to toxins in utero has also been implicated as a cause.[39–41,43]

Clinical signs similar to those of spastic paresis are seen in horses with “shivers.” Shivers is most commonly seen in draft horse breeds, warmbloods, and warmblood crosses >1 year of age, although it may occur in light horse breeds.[44] Suggested causes include genetic, traumatic, infectious, and neurologic diseases, although its exact basis is unknown. The disease primarily affects the hindlimbs and is characterized by periodic, involuntary spasms of the muscles in the pelvic region, pelvic limbs, and tail that are exacerbated by backing or picking up the hindlimbs. The affected limb is elevated and abducted and may actually shake and shiver, and the tail head is usually elevated concurrently and trembles (Fig. 42-2). In more severely affected animals, on backing up the hindlimb is suddenly raised, semiflexed, and abducted with the hoof held in the air for several seconds or minutes; the tail is elevated simultaneously and trembles. After a variable period of time, the spasms

subside, the limb is extended, and the foot is brought slowly to the ground. There are no distinct myotonic discharges on EMG with shivers, indicating it is not a true myotonic condition.

42.5.1.1 Myotonia

42.5.1.1.1 Clinical Signs

Myotonia congenita in humans, horses, and goats is usually detected in the first year of life.[45–48] Affected animals commonly have conspicuously well-developed musculature and display mild pelvic limb stiffness. Gait abnormalities are usually most pronounced when exercise begins and frequently diminish as exercise continues. Bilateral bulging (dimpling) of the thigh and rump muscles is often obvious and gives the impression that the animal is very well developed (Fig. 42-3). Stimulation of affected muscles, especially percussion, exacerbates the muscle dimpling below a large area of tight contraction (Fig. 42-4). Affected muscles may remain contracted for up to a minute or more, with subsequent slow relaxation.[37,48,49]

In goats, myotonia congenita appears to an autosomal dominant mutation in the skeletal muscle chloride channel that has incomplete penetrance.[31,47,50] Affected goats are commonly referred to as “fainting goats.” Signs are usually recognizable by 6 weeks of age and vary from stiffness after rest to marked general rigidity after visual, tactile, or auditory stimulation. Clinical signs remain throughout the animal's life but are not progressive.[51]

1393

1394

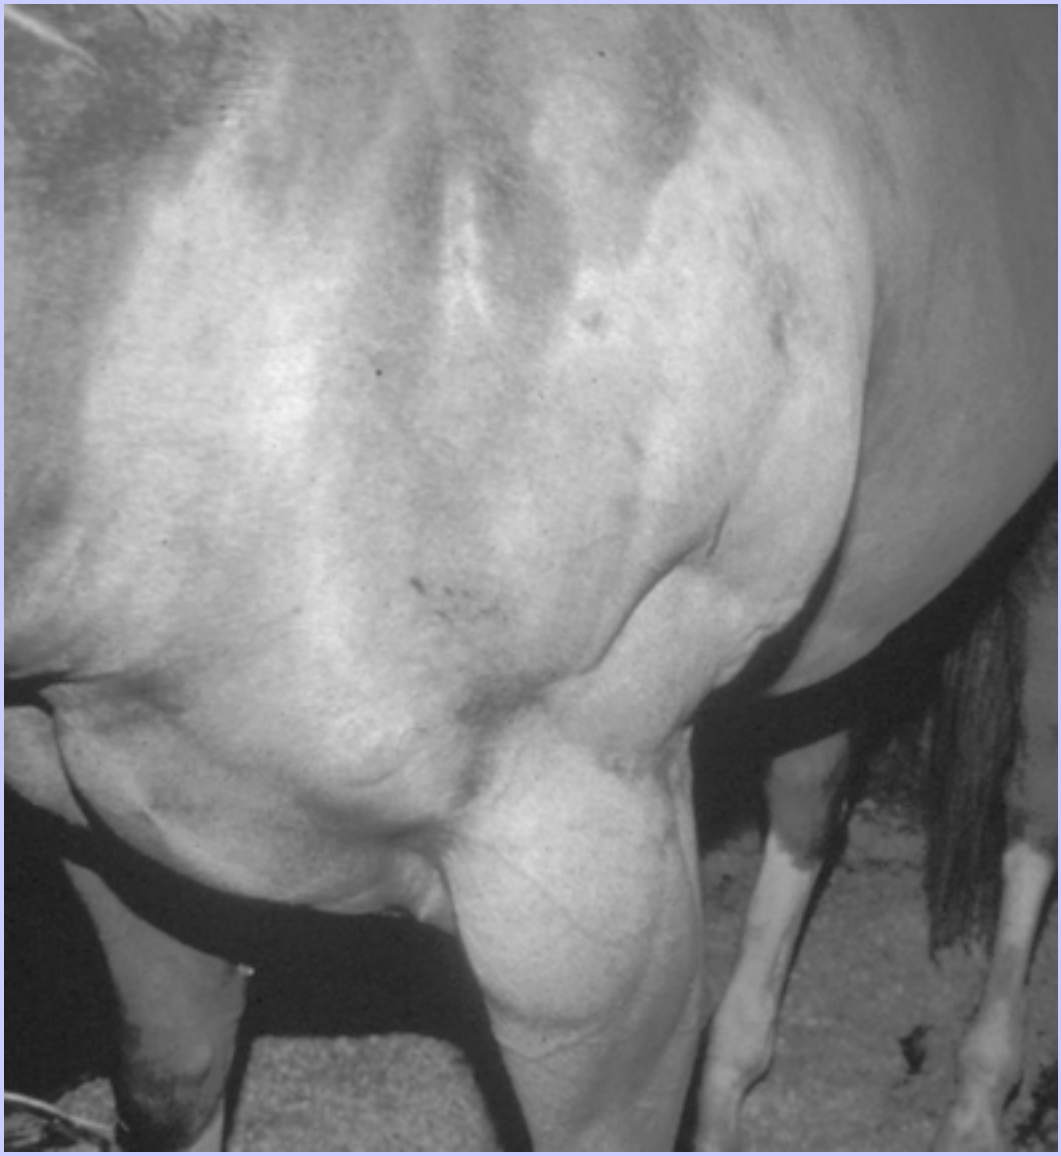
B

Fig. 42-4 Myotonic dimpling of the triceps in a horse with hyperkalemic periodic paralysis.



Myotonia congenita does not usually show progression of clinical signs beyond 6 to 12 months of age in horses.[37] To date no abnormalities in sarcolemmal chloride conductance have been demonstrated in horses, and an inherited basis has not been established in horses.

Myotonia dystrophica appears to be a separate form of myotonia in horses.[36,37,52] Severe clinical signs of myotonia that progress to marked muscle atrophy and possibly involve a variety of organ systems have been observed in quarter horse, Appaloosa, and Italian-bred foals. Retinal dysplasia, lenticular opacities, and gonadal hypoplasia have been reported in one such quarter horse foal.[36] This condition resembles

myotonia dystrophica in humans, which is caused by genetic mutations involving either the *DMPK* gene or the *ZNF9* gene.[53,54] In both cases a short segment of DNA is abnormally repeated many times, forming an unstable region in the gene, which alters mRNA processing. The genetic basis of myotonic dystrophy in horses is not yet known.

42.5.1.1.2

Diagnosis

A tentative diagnosis frequently can be made on the basis of age, clinical signs (stiff gait, particularly at the onset of exercise), muscle bulging, and prolonged contractions after muscle stimulation.

1394

1395

Definitive diagnosis of myotonia is usually based on electromyographic examination. Affected muscle manifests pathognomonic, crescendo-decrescendo, high-frequency repetitive bursts with a characteristic "dive bomber" sound.[36,52,55] This sound is produced by the repetitive firing (after contractions) of affected muscle fibers. After a contraction diminishes, the excitability of muscle fibers is decreased, and the action potentials recorded by EMG reflect the diminution of electrical activity.[56]

Muscle biopsy samples from foals with myotonia congenita may be normal or may demonstrate extremely variable muscle fiber dimensions up to twice those of normal age-matched controls.[48] Type I fiber hypertrophy may be seen with accompanying signs of fiber splitting. The major changes noted with myotonic dystrophy are ringed fibers, alterations in the shape and position of myonuclei, sarcoplasmic masses, and an increase in endomysial and perimysial connective tissue.[36,37,52,57] Fiber type grouping and atrophy of both type I and type II muscle fibers may be present.

42.5.1.1.3

Treatment

Considering that the pathophysiologic basis of myotonia in horses has not been clearly identified, recommendations for specific, effective therapy are almost impossible. In affected humans and dogs some relief of signs has been provided by drugs such as quinine, procainamide, and phenytoin. However, responses vary among patients. Phenytoin has been reported to be efficacious in two quarter horses with HYPP and myotonic dystrophy.[55]

42.5.1.1.4

Prognosis

Prognosis appears to be variable and dependent on the severity of clinical signs. Mildly affected animals may undergo some amelioration of clinical signs with increasing age. In animals that exhibit mild clinical signs, manifestations of the disorder may abate over a period of months to years. The reason(s) for this regression of signs is unknown. Other more severely affected horses may have progression of signs, including atrophy and fibrosis or pseudohypertrophy to the point at which the animal is no longer able to move without great pain and difficulty (Fig. 42-5). Euthanasia of such animals is often warranted.

Although conclusive evidence regarding the genetic basis of this disorder in horses is still not available, owners of affected horses should be cautioned about the possibility that this disease is heritable.

Fig. 42-5 Marked progressive atrophy of the epaxial and gluteal muscles of a horse with myotonic dystrophy.

42.5.1.2

Hyperkalemic Periodic Paralysis

SHARON J. SPIER

Equine HYPP is caused by an inherited defect in the skeletal muscle sodium channel.[35,58–61] This myopathy manifests as abnormal skeletal muscle membrane excitability leading to episodes of myotonia, or sustained muscle contraction, and paralysis. In humans, numerous muscle membrane channel defects (so-called "channelopathies") have been characterized, and the molecular basis for disease is well described.[46] Other reported disorders with suspected membrane defects in horses include myotonic dystrophy and congenital myotonia.[36,48] HYPP was the first equine disease attributed to a specific genetic mutation and detectable through DNA technology.[60]

HYPP is an autosomal dominant trait affecting quarter horses, American Paint horses, Appaloosas, and quarter horse cross-bred animals worldwide. A "syndrome" in related horses was first recognized in the 1980s by breeders and veterinarians and was first reported to be similar to HYPP in humans by Cox at the American Association of Equine Practitioners (AAEP) convention in 1985.[61] In December 2002, this genetic disease was publicly linked to a popular quarter horse sire named Impressive. This prolific sire, born in 1969, has 355,000 offspring registered with the American Quarter Horse Association (AQHA),[*] and these

offspring dominate the halter horse industry. Current estimates indicate that 4% of the quarter horse breed may be affected.[62] Unfortunately, the gene frequency has not decreased in the past 14 years since genetic testing has been available to breeders, and controversy continues among horse breeders whose stock carry this gene.[†] Affected horses appear to have been preferentially selected as breeding stock because of their pronounced muscle development, and there is evidence of selection of HYPP-affected horses as superior halter horses by show judges.[63] In 1996 AQHA officially recognized HYPP as a genetic defect or undesirable trait. To increase public awareness of this genetic defect, mandatory testing for HYPP with results designated on the registration certificate began for foals descending from Impressive born after January 1, 1998. In response to requests from the membership, in 2004 the AQHA Stud Book and Registration Committee ruled that foals born in 2007 and later testing homozygous affected for HYPP (H/H) will not be eligible for registration. Breeders opposed to restrictions argue that the disease can be controlled through diet and medication and that these horses are highly successful in the show ring.[64]

* Griffith G, AQHA Registrar. Personal communication, 2005.

† Statistics from UCD Veterinary Genetics Laboratory HYPP Testing, 2006.

42.5.1.3

Clinical Signs

Clinical signs among horses carrying the same mutation range from none (horses are asymptomatic) to daily muscle fasciculations and weakness. In the majority of horses, intermittent clinical signs begin by 2 to 3 years of age with no apparent abnormalities between episodes.[35,59] Ingestion of diets high in potassium (>1.1%), such as those containing alfalfa hay, molasses, electrolyte supplements, and kelp-based supplements or sudden dietary changes commonly trigger episodes.[65] Fasting, anesthesia or heavy sedation, trailer rides, and stress may also precipitate clinical signs; however, the onset of signs is often unpredictable and without a definable cause. Other possible precipitating factors that have been noted in humans and horses are exposure to cold, fasting, pregnancy, and concurrent disease and rest after exercise. Exercise per se does not appear to stimulate clinical signs, and serum CK shows no change or only modest increases during episodic fasciculations and weakness.

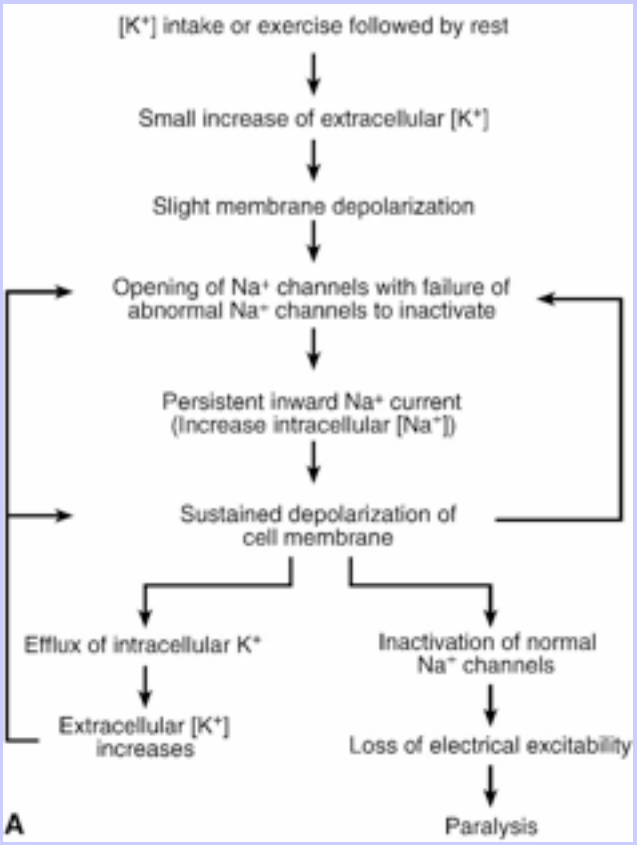
1395

1396

In most cases clinical episodes begin with a brief period of myotonia, with some horses showing prolapse of the third eyelid. Sweating and muscular fasciculations are observed commonly in the flanks, neck, and shoulders. The muscle fasciculations become more generalized as additional muscle groups are involved. Stimulation and attempts to move may exacerbate muscular tremors. Some horses may develop severe muscle cramping. Muscular weakness during episodes is a common characteristic of HYPP. Horses remain standing during mild attacks. In more severe attacks, clinical signs may progress to apparent weakness with swaying, staggering, dog sitting, or recumbency within a few minutes. Heart and respiratory rates may be elevated, and horses may show manifestations of stress (anxious appearance) yet remain relatively bright and alert during episodes. Affected horses usually respond to noise and painful stimuli during clinical manifestations of the disorder. Episodes last for variable periods, usually from 15 to 60 minutes. Several horses have died during acute episodes.[1] Respiratory distress occurs in some animals as a result of paralysis of upper respiratory muscles, and a tracheostomy may be necessary. In addition, young horses that are homozygous for the HYPP trait have been observed to manifest respiratory stridor and periodically may develop obstruction of the upper respiratory tract. Horses homozygous for HYPP may have dysphagia or respiratory distress, and endoscopic findings include pharyngeal collapse and edema, laryngopalatal dislocation, and laryngeal paralysis.[66] After the episode subsides, horses regain their feet and appear normal with no apparent or minimal gait abnormalities. Although horses with HYPP appear normal between attacks,

electromyographic examination of affected horses reveals abnormal fibrillation potentials, complex repetitive discharges with occasional myotonic potentials, and trains of doublets between episodes.[35,67]

Fig. 42-6 A, Explanation for paralytic attacks in horses with hyperkalemic periodic paralysis (HYPP). B, A horse suffering from an episode of HYPP-associated collapse after exposure to a cool rain shower.



42.5.1.4 Etiology

HYPP results from a point mutation that results in a phenylalanine-leucine substitution in a key part of the voltage-dependent skeletal muscle sodium channel alpha subunit.[60] In horses with HYPP, the resting membrane potential is closer to firing than in normal horses.[68] Sodium channels are normally briefly activated during the initial phase of the muscle action potential. The HYPP mutation results in a failure of a subpopulation of sodium channels to inactivate when serum potassium concentrations are increased. As a result, an excessive inward flux of sodium and outward flux of potassium ensues, resulting in persistent depolarization of muscle cells and temporary weakness (Fig. 42-6).

42.5.1.5

Diagnosis

Descent from the stallion Impressive on the sire's or dam's side in a horse with episodic muscle tremors, weakness, or collapse is strongly suggestive of HYPP. Quarter horse foals born after 1998 that are offspring of an affected parent have a statement recommending DNA testing for HYPP on the Certificate of Registration. In most cases hyperkalemia (6 to 9 mEq/L), hemoconcentration, and mild hyponatremia occur during clinical manifestations of the disease, with normal acid-base balance.[35] Serum potassium concentration returns to normal after the abatement of clinical signs. Some affected horses may have normal serum potassium concentrations during minor episodes of muscle fasciculations.[59] Differential diagnoses for hyperkalemia include delay before sample centrifugation, hemolysis, acidosis, renal failure, severe rhabdomyolysis, and high-intensity exercise.

Because veterinarians may not be present during acute episodes, the definitive test for identifying HYPP is the demonstration of the base-pair sequence substitution in the abnormal segment of the DNA encoding for the alpha subunit of the sodium channel.[60] Submission of mane or tail hair with hair root should be made to a licensed laboratory such as the Veterinary Genetics Laboratory at the University of California, Davis (www.vgl.ucdavis.edu). 1396 1397

42.5.1.6

Treatment

Mild exercise can sometimes abort an episode in mild cases or if horses are just beginning to exhibit clinical signs. Feeding grain or corn syrup to stimulate insulin-mediated movement of potassium across cell membranes may also be helpful. Other treatment options that may abort an episode include intramuscular administration of epinephrine (3 mL of 1:1000 per 500 kg) and administration of acetazolamide (3 mg/kg orally [PO] every 8 to 12 hours). Many horses experience spontaneous recovery from episodes of paralysis and appear normal by the time a veterinarian arrives.

In severe cases, administration of calcium gluconate (0.2 to 0.4 mL of a 23% solution per kilogram, diluted in 1 L of 5% dextrose) will often provide immediate improvement. An increase in extracellular calcium concentration raises the muscle membrane threshold potential, which decreases membrane hyperexcitability. To reduce serum potassium, intravenous dextrose (6 mL of a 5% solution per kilogram) alone or combined with sodium bicarbonate (1 to 2 mEq/kg) can be used to enhance intracellular movement of potassium. With severe respiratory obstruction, a tracheostomy may be necessary.

42.5.1.7

Control

Decreasing dietary potassium and increasing renal losses of potassium are the primary steps taken to prevent HYPP episodes. Feedstuffs to avoid include high-potassium feeds such as alfalfa hay, orchard grass hay, brome hay, soybean meal, sugar molasses, and beet molasses. Optimally, later cuts of timothy or Bermuda grass hay and grains such as oats, corn, wheat, and barley, and beet pulp should be fed in small meals several times a day (Table 42-1). Regular exercise and/or frequent access to a large paddock or yard are also beneficial. Pasture works well for horses with HYPP because the high water content of pasture grass makes it unlikely that horses will consume large amounts of potassium in a short period of time. Ideally, horses with recurrent episodes of HYPP should be fed a balanced diet containing between 0.6% and 1.1% to 1.5% total potassium concentration and meals containing less than 33 g of potassium.[65,69,70] Horses will adapt to diets higher in potassium over a period of 2 weeks and will experience fewer fluctuations in potassium in blood with subsequent decreased frequency of clinical signs.[69] Because there is wide variation in potassium concentration of forages depending on maturity and soils, it is advisable to have feeds analyzed for potassium concentrations and other nutrients.[70] The table below contains examples of feeds containing varying concentrations of potassium. Supplement with vitamin E, selenium, salt, and balanced minerals where indicated to meet nutritional requirements. Commercially available complete feeds with a guaranteed K^+ content may be more convenient for some HYPP horses, especially for owners with few horses.

Table 42-1 Examples of Feed Containing High, Medium, or Low Concentrations of Potassium (K^+)

	K^+ (%)	g K^+/lb of feed
High-Potassium Feed		
Electrolyte supplements	30	136
Molasses	6	27
Kelp supplements	4	18
Alfalfa hay (90% DM)	1.4-2.4	6.4-10.9
Canary grass hay	2.6	2.6
Orchard grass hay	2.4-2.6	10.9-11.8
Soybean meal	2	9.1
Medium-Potassium Feed		
Fescue hay	1.7-2.1	7.7-9.5
Rice bran	1.8	8.1
Timothy hay	1.4-2.1	6.4-9.5
Coastal Bermuda hay	1.2-1.9	5.5-8.2
Kentucky bluegrass hay	1.4	6.4
Oat hay	1.4	6.4
Low-Potassium Feed		
Pure fats and oils	0	0
Beet pulp	0.2-0.3	0.9-1.4
Corn, oats, or barley	0.3-0.5	1.4-2.3
Pasture grass (23% DM)	0.3-0.8	1.4-3.6
Wheat	0.4	1.8
Wheat bran	1.2	5.45
Soybean hulls	1.2	5.45

DM, Dry matter.

To decrease the frequency of episodes, avoid high-potassium feed; select feed that contains medium to low K^+. Feeding a balanced ration containing less than 1.5% K^+ and meals <33 g K^+ decreases fluctuations of blood K^+, lowering the frequency of hyperkalemic periodic paralysis symptoms.[12,15,16]

For horses with recurrent episodes of muscle fasciculations even with dietary alterations, acetazolamide (2 to 3 mg/kg PO every 8 to 12 hours) or hydrochlorothiazide (0.5 to 1 mg/kg PO every 12 hours) may be helpful. These agents exert their effects through different mechanisms; however, both cause increased renal potassium excretion. In addition, acetazolamide stabilizes blood glucose and potassium by stimulating insulin secretion. Breed registries and other associations may have restrictions on the use of these drugs during competitions, as diuretics may mask prohibited substances.

1397
1398

42.5.1.8 Prognosis

In most cases HYPP is a manageable disorder, although recurrent bouts may occur and severe episodes can be fatal. Owners of affected horses should be strongly discouraged from breeding these animals for the long-term health of the quarter horse and other breeds. As this is a dominant trait, breeding an affected horse to a normal horse results in a 50% chance of producing a foal with HYPP. All affected horses share the same mutation, regardless of whether or not owners have witnessed signs in their horses.[71] Affected horses are not suitable for young or inexperienced riders. Owners of affected horses should advise veterinarians of HYPP status before anesthesia or procedures requiring heavy sedation, as these circumstances could precipitate an episode of paralysis.

42.6 MUSCLE CRAMPING

STEPHANIE J. VALBERG

GARY CARLSON

Muscle cramps are a painful condition that arises from hyperactivity of motor units caused by repetitive firing of the peripheral and/or central nervous system. The origin of the cramp in most cases is believed to be the intramuscular portion of the motor nerve terminals.[29,72] Most muscle cramps are also accompanied by fasciculations in the same muscle. Muscle cramps can be induced by forceful contraction of a shortened muscle, by changes in the electrolyte composition of extracellular fluid, and by ear tick infestations in horses.[29,38] In contrast, muscle contractures are painful muscle spasms that represent a state of muscle contracture unaccompanied by depolarization of the muscle membrane.[72] Muscle contractures occur with MH and some forms of exertional myopathies and are invariably accompanied by markedly increased serum CK activity.

42.6.1 Dietary Electrolytes

Some horses develop muscle stiffness and occasional elevations in serum CK when fed a diet deficient in sodium or potassium. These chronic deficiencies are rarely reflected in serum electrolyte concentration but may be detected by performing renal FE of electrolytes.[11] Sodium deficiency is particularly common because forage and grain diets are low in sodium and chloride and high in potassium. Supplementation of the equine diet with salt is a necessity. Salt blocks may not be adequate in this regard, and loose salt (1 to 2 oz) added directly to the grain is often the best mechanism of supplementing horses with salt. Some horses may require higher dietary salt supplementation to maintain an adequate sodium balance. Balancing dietary electrolytes has been reported to decrease muscle cramping and serum CK activity in those horses with dietary deficiencies.[11]

42.6.2 Exhaustion in Endurance Horses

Muscle cramping in endurance horses occurs commonly during prolonged exercise in hot weather, particularly when the humidity is high.[73,74] Under such circumstances rectal temperatures reach as high as 41° C and horses may lose up to 15 L/hr of fluids in the form of sweat that is rich in sodium, potassium, and chloride.[75,76]

42.6.2.1 Clinical Signs

Affected horses demonstrate stiffness and cramping in the muscles of locomotion. Pain is a characteristic of the disorder, and affected muscle groups often undergo periodic spasms. In addition, exhausted horses are often dull, depressed, and clinically dehydrated with elevated heart and respiratory rates and persistently elevated body temperature. Common electrolyte abnormalities include hypochloremic metabolic alkalosis with hypokalemia, hypomagnesemia, and low serum ionized calcium concentrations.[73,74,77] Synchronous diaphragmatic flutter (SDF) may be seen in association with cramping.[73]

Although many of the signs of muscular dysfunction are similar to those of ER, affected horses do not generally develop myoglobinuria.[73]

42.6.2.2 Etiology

Factors contributing to cramping are dehydration, electrolyte abnormalities, and disturbances in thermoregulatory and local circulatory function. Whether this disorder is similar to heat cramps seen in human athletes is not known.

42.6.2.3 Diagnosis

A variety of electrolyte abnormalities occur in affected animals.[73,77] Mild cases are distinguished by the presence of muscle cramps that subside with rest or light exercise in heat-stressed horses. In more severe cases clinical signs of dehydration and shock are often present. Horses with muscle cramping will not have marked elevations in serum CK or AST, nor will they exhibit myoglobinuria. Exhausted horses, however, may progress to develop rhabdomyolysis with marked electrolyte derangements. These horses require immediate treatment.

42.6.2.4 Treatment

Under most circumstances the mild form of muscle cramping is self-limiting, and the signs abate with rest or light exercise. However, if evidence of other metabolic derangements exists, treatment for these disorders (e.g., plasma volume expansion with oral or intravenous isotonic polyionic fluids, cooling using water and fans) is frequently beneficial to the horse.[78] Because most horses with this condition are alkalotic, administration of solutions containing sodium bicarbonate is contraindicated. Dietary analysis should be performed to determine the extent of salt and electrolyte supplementation necessary in affected horses. Daily direct addition of 2 oz of sodium chloride and 1 oz of potassium chloride to the feed is recommended for horses with recurrent cramping in addition to electrolyte supplementation before and after endurance rides.

42.6.3 Synchronous Diaphragmatic Flutter

SDF, also known as “thumps,” usually occurs in horses with derangements in fluid and electrolyte balance. Inciting causes include endurance exercise, hypocalcemia, hypoparathyroidism, digestive disturbances, and possibly the administration of medications. A characteristic clinical manifestation of the disease occurs when the diaphragm contracts in synchrony with atrial depolarization.[79–81]

42.6.3.1 Clinical Signs

The classic sign of SDF is a contraction or twitch in the flank region (unilateral or bilateral) as the diaphragm contracts synchronously with the heart. In severe cases this twitch may produce an audible thumping sound.

The metabolic derangements leading to SDF also may be clinically apparent in some cases. These may include signs of dehydration and volume depletion. Endurance horses with SDF in association with the exhausted horse syndrome may demonstrate dehydration, inappropriate sweating responses, persistently elevated body temperature, depression, anorexia, and aperistalsis.[73,74] In some horses, SDF may be a chronic, recurring problem.[79]

1398

1399

42.6.3.2 Etiology

A variety of stimuli may result in SDF. These include prolonged exercise, particularly during hot weather; hypocalcemia resulting from lactation, transit, or stress; digestive tract dysfunction; furosemide therapy; trauma; and primary hypoparathyroidism.[79,81] The most consistent metabolic derangement reported in horses with SDF is low serum ionized calcium concentrations, usually associated with hypochloremic metabolic alkalosis.[79,80] Metabolic alkalosis may alter the ratio of free to bound calcium (increasing calcium binding to protein and decreasing ionized calcium), which possibly induces SDF.

SDF occurs in association with atrial depolarization in horses. It has been postulated that fluid, electrolyte, and acid-base derangements may disrupt the normal membrane potential of the phrenic nerve, which passes directly over the atrium, resulting in nerve discharges in response to atrial depolarization.[79,80,82]

42.6.3.3 Treatment

In most cases SDF is a transient event, usually abating when the underlying cause resolves, either spontaneously or in response to treatment.[79] Most horses undergo rapid remission of signs when given calcium solutions intravenously (IV) as described in the section on hypocalcemia in horses. Although hypomagnesemia is often present with SDF, horses do not respond to magnesium supplementation unless calcium is administered concurrently. Response to therapy is also reflected by improved mental status, return of appetite, and gut motility.[79]

42.6.3.4 Control

Electrolyte supplementation and some dietary manipulations may help reduce the incidence of SDF in some endurance horses that experience recurrent bouts. Provision of chloride, potassium, and sodium during prolonged exercise may help reduce fluid losses and the metabolic alkalosis that commonly accompanies this form of exercise and frequently occurs in association with SDF. Metabolic alkalosis decreases the amount of free calcium available. Supplementation of calcium and magnesium during endurance rides has been suggested to be helpful in horses prone to SDF.

suggested to be helpful in horses prone to SDF.

Alternative approaches involve reduction of dietary calcium in horses prone to SDF for a few days before an endurance ride. It is postulated that this reduction in dietary calcium stimulates the endocrine homeostatic mechanisms and increases osteoclastic activity. In the short term the horse depends less on dietary calcium and is able to mobilize substantial amounts of calcium in response to the demands imposed by the exercise; calcium losses in sweat are overcome by the release of calcium from endogenous storage pools (bone).[79] Furthermore, horses routinely fed alfalfa hay, which has a relatively high calcium concentration, may be more prone to development of SDF. Limitation of this feedstuff may be indicated in chronically affected horses.

42.6.4 Hypocalcemia in Horses

Hypocalcemia is a relatively rare disorder in horses that has also been referred to as *lactation tetany, transport tetany, idiopathic hypocalcemia,* and *eclampsia*.

42.6.4.1 Clinical Signs

Clinical signs are variable and include increased muscle tone; a stiff, stilted gait; rear limb ataxia; muscle fasciculations (especially temporal, masseter, and triceps muscles); trismus; dysphagia; salivation; anxiety; profuse sweating; tachycardia; elevated body temperature; cardiac dysrhythmias; SDF; convulsions; coma; and death.[83,84] Clinical signs may be remarkably similar to some of those seen with tetanus. This disorder may be progressive (in lactating mares in particular) over a 24- to 48-hour period, and some animals die. Clinical signs are related to the magnitude of the serum calcium concentration. Increased excitability is usually the only sign when values are below normal but above 8 mg/dL. Values of 5 to 8 mg/dL usually produce tetanic spasms and incoordination. Concentrations below 5 mg/dL usually result in recumbency and stupor.

42.6.4.2 Etiology

Loss of calcium in milk, especially in mares that produce large amounts of milk, seems to predispose to this disorder.[83,84] Other factors such as heavily lactating mares grazing lush pastures, hard work, prolonged transport, and ingestion of blister beetles (cantharidin toxicosis) may precipitate attacks.

42.6.4.3 Diagnosis

Clinical signs often are highly suggestive of hypocalcemia in affected horses. Historic aspects such as lactation, previous prolonged exercise, or transport also may direct the clinician to the suspected diagnosis.[83]

Definitive diagnosis depends on laboratory demonstration of hypocalcemia, with total calcium concentrations as low as 4 to 6 mg/dL in some cases. In addition, metabolic alkalosis, hypomagnesemia or hypermagnesemia, and hyperphosphatemia or hypophosphatemia have all been found in association with hypocalcemia in horses.[83] These alterations may need correction before a return to normal function is seen in some affected animals.

42.6.4.4

42.6.4.4 Treatment

Although many animals with mild cases recover without specific treatment, in others this disorder may be life-threatening. Therefore therapy is to be encouraged in most cases. Treatment involves the intravenous administration of calcium solutions such as 20% calcium borogluconate or those recommended for the treatment of parturient paresis in cattle.[83] Administration of these solutions at the rate of 250 to 500 mL/500 kg diluted 1:4 with saline or dextrose often results in full recovery, although in some cases it may take several days.[83] Relapses do occur. These preparations should be administered slowly in conjunction with close monitoring of the cardiovascular response. Dilution in saline or dextrose before infusion decreases the chance of cardiotoxicity. Normally there is a positive inotropic effect in response to calcium administration.[85] However, alterations in rate or rhythm provide evidence to suspend the infusion. If no response to an initial infusion occurs, a second dose may be given 15 to 30 minutes later. Most cases respond to this form of therapy, although in some cases in which signs persist, repeated treatments may be necessary.

42.6.5 Ear Tick—Associated Muscle Cramping

Intermittent painful muscle cramps have been described in a small number of horses with severe *Otobius megnini* infestations.[38] Muscle cramping is not associated with exercise. These horses show intermittent signs of severe muscle cramping of pectoral, triceps, abdominal, or semitendinosus or semimembranosus muscles lasting from minutes to a few hours, with severe pain that often resembles colic. Horses may fall over when stimulated. Between muscle cramps horses appear to be normal. Percussion of triceps, pectoral, or semitendinosus muscles results in a typical myotonic cramp. Horses have elevated serum CK levels ranging from 4000 to 170,000 IU/L. Numerous ear ticks, *O. megnini,* can be identified in the external ear canal of affected horses. Without treatment for ear ticks, the spasms continue; however, local treatment of the ear ticks using pyrethrins and piperonyl butoxide results in recovery within 12 to 36 hours. Acepromazine may be helpful to relieve painful cramping.

42.7 NONEXERTIONAL RHABDOMYOLYSIS

42.7.1 INFLAMMATORY MYOPATHIES

42.7.1.1 Clostridial Myonecrosis

STEVEN M. PARISH

STEPHANIE J. VALBERG

Various species of clostridial organisms cause acute myonecrosis in many farm animal species. Infections are characterized by a rapid clinical course, fever, systemic toxemia, and high mortality.[86–88] Clostridial diseases are infectious but not contagious. Specific bacteria associated with clostridial myonecrosis include *Clostridium chauvoei (Clostridium welchii), Clostridium septicum, Clostridium sordelli,* and occasionally *Clostridium novyi* type B, *Clostridium perfringens* type A, and *Clostridium carnis*. Mixed infections involving several agents are common.[89] Synonyms for clostridial diseases include *blackleg, malignant edema, false blackleg, gas gangrene,* and *gangrene*. Although there may at times be distinct differences among the specific disease syndromes associated with the different clostridial agents, the pathophysiology of

these diseases is similar enough to be covered under the general topic of clostridial myonecrosis.

42.7.1.1.1

Clinical Signs

Commonly, clostridial myonecrosis is rapidly progressive with the development of tremors, ataxia, dyspnea, recumbency, coma, and death within 12 to 24 hours. Therefore many affected animals may be found prostrate or dead.[86,87] Mortality may approach 100%. Affected animals that are still alive are usually severely depressed, febrile (40° C to 41° C [104° F to 106° F]), tachypneic, anorectic, and lame. These signs are associated with a rapidly developing muscle infection and toxemia. There is usually only one primary site of infection in an affected animal. Any skeletal muscle group in the body can be involved, but most infections affect the limb or trunk muscles. Occasionally muscles such as those around the vulva, tongue, and diaphragm can be involved, or the udder in a cow may be the primary site of sepsis. Areas around recent injections are common sites of myonecrosis in the horse.[88,90] Initially the skin over the area may be swollen, hot, and discolored; however, as the disease progresses the skin over the area may become cool and insensitive with progressive sloughing. Crepitus may be detectable, indicating subcutaneous gas production. If a wound is present, malodorous, serosanguineous fluid may discharge (Fig. 42-7). Aspiration of the swelling often reveals fluid with similar qualities.

Clostridial myonecrosis generally has characteristic pathologic lesions that are absent in most other conditions, making diagnosis relatively straightforward. Differential diagnoses may include other fulminant disease processes in which there is rapid debilitation or death of the animal.

42.7.1.1.2

Clinical Pathology

Clinicopathologic data alone are seldom specific enough to confirm the presence of clostridial myonecrosis. Hematology and serum biochemical analyses usually reflect a generalized state of debilitation and toxemia (e.g., hemoconcentration and a stress or toxic leukogram may be present). Elevations in the activities of serum CK and serum AST usually occur; however, they often do not reflect the toxicity of clostridial myonecrosis.

Fig. 42-7 Clostridial myositis in the right gluteal muscle after an injection of flunixin meglumine which has progressed to involve the

biceps femoris muscle. Fenestrations were created for debridement.

Aspirates from the affected tissues can yield diagnostic information. It is preferable to obtain tissue specimens for direct smear examination and fluorescent antibody testing, and for anaerobic bacterial culture from affected tissues.

culture from affected tissues.

42.7.1.1.3

Pathophysiology

Clostridial agents are ubiquitous in the environment and can frequently be cultured from the feces, intestinal tract, and other internal organs of a variety of species.[86] Spore-forming characteristics allow these organisms to remain in the environment for long periods, but the exact mechanisms involved in the pathogenesis of clostridial myonecrosis are not fully known. Development of clostridial myonecrosis after an intramuscular injection or penetrating wound may be the result of direct spore deposition into the tissue in association with penetration. If suitable conditions prevail within the muscle, the spores undergo a conversion into the vegetative, toxin-producing form of the organism. In contrast, the pathogenesis of the disease is more difficult to explain when a wound does not exist. It is postulated that clostridial agents gain access to the body through the alimentary tract and are present in liver and muscle in the dormant spore form.[91] Subsequently, when local tissue is devitalized and conditions become appropriate for the spores to germinate, the rapid vegetative process ensues. Muscle trauma associated with injection, transporting, herding, and handling has often been incriminated as creating a suitable environment for the development of clostridial myonecrosis. The proliferation of clostridial agents in devitalized tissues is associated with the release of powerful exotoxins responsible for the local necrotizing myositis and systemic toxemia. Toxins are released by multiplying clostridia; the toxins vary, depending on the clostridial species involved. Necrotizing (lecithinase) and hemolyzing (hemolysin) toxins as well as neuraminidase appear to be of greatest importance. The toxins act locally and systemically to create widespread organ dysfunction. The toxins of *C. sordelli* are the most potent of all the clostridial species, and myonecrosis caused by this organism is fatal.

1400

1401

42.7.1.1.4

Epidemiology

Clostridial agents are common in the environment, and susceptible animals are constantly exposed to them. Areas where previous death losses from clostridial disease have occurred may have a higher incidence or risk of disease because of increased environmental contamination. In cattle clostridial myonecrosis is generally a disease of animals between 4 and 24 months of age. However, *C. sordelli* is a more common problem in older feedlot cattle, in which excessive muscle bruising may occur. Younger animals are probably protected by colostral immunity and older animals by some degree of acquired immunity. Animals on high planes of nutrition and in excellent body condition are more likely to develop the disease. Infections with *C. chauvoei* occur most commonly during the warmer seasons, with the highest incidence varying from the spring to fall, depending on when calves reach the most susceptible age group. *C. septicum, C. novyi,* and *C. perfringens* type A infections can occur at any time and are usually associated with skin wounds such as injection sites, punctures, and castration wounds. The umbilicus may be a site of invasion. Infections in the genital area can occur, usually in association with a recent dystocia.

In sheep and goats, clostridial myonecrosis is most frequently associated with wounds such as those occurring after shearing, docking, and unsanitary surgical procedures. Sheep dipped for parasites after shearing may have an increased risk if the dip becomes contaminated with clostridial spores.

Most reports of clostridial myonecrosis in horses suggest an association with puncture wounds and intramuscular injection sites.[88,90] Intramuscular administration of irritating drugs (including antihistamines, anthelmintics, and phenylbutazone) may enhance the susceptibility to clostridial

antihistamines, antihelmintics, and phenylbutazone) may enhance the susceptibility to clostridial myonecrosis. Horses often are presented with or have a history of another complaint such as colic, exertional myopathy, or laminitis for which they have received injections of drugs in the preceding 48 hours.[92] Previously administered drugs (e.g., phenylbutazone) may mask the fever associated with clostridial myonecrosis, potentially confusing the diagnosis.

42.7.1.1.5

Necropsy Findings

Swelling and autolysis are rapid in animals that have died from clostridial myonecrosis. Bloodstained fluid is often observed discharging from body orifices. Extreme swelling and crepitus may be noted over the affected body area. When acting alone, each of the clostridial agents associated with clostridial myonecrosis produces somewhat different postmortem lesions. However, it is unwise to assume that in clostridial myonecrosis only a single clostridial agent was involved, because mixed infections frequently occur.

C. chauvoei infection is characterized by engorgement of the subcutis and adjacent tissues with bloodstained fluids and gas bubbles. Cut tissue from the affected area reveals moist, dark-colored muscle in the periphery of the lesion, with lighter-colored, drier muscle with gas bubbles separating the separate bundles of muscle toward the center. Other changes include severe degeneration of parenchymatous tissues caused by the systemic toxemia. The carcass usually has a foul odor similar to that of rancid butter. This odor is a characteristic of most cases of clostridial myonecrosis. The lungs are often congested with edema, and hemorrhage and a fibrinohemorrhagic pleuritis are common. The heart may be friable and show evidence of endocardial hemorrhages, particularly on the right side. The spleen may be normal or enlarged and friable. The liver is usually pale and friable and may be autolytic and porous. Lesions are similar in sheep and cattle, except that there is usually less gas and the muscles are not as dry in affected sheep.

Similar necropsy findings are found with myonecrosis caused by *C. septicum* and *C. novyi* type B. *C. septicum* and *C. perfringens* generally occur as part of mixed wound infections in which abundant malodorous, serosanguineous fluid is found at the wound site. *C. perfringens* is common in horses.

Myonecrosis resulting from *C. sordelli* is most often associated with lesions of the neck or brisket area of cattle. Death is frequently so rapid that subcutaneous gas accumulation is rare. In addition to local myonecrosis, these animals often have massive subendocardial hemorrhages in the left ventricle of the heart and hemorrhage in the trachea, bronchi, and thymus. Extensive perirenal edema and hemorrhagic renal calyces and severe congestion of the lungs are common findings.

42.7.1.1.6

Treatment

Although clostridial myonecrosis is often fatal, aggressive specific therapy combined with supportive care may be successful in individual cases. A presumptive diagnosis of clostridial disease on the basis of history and clinical signs is usually made before obtaining the results of culture and laboratory determinations such as fluorescent antibody tests. In horses, clostridial myonecrosis resulting from infections with *C. perfringens* seems to be most amenable to treatment and has the best prognosis for survival, although extensive skin sloughing over the affected area is common.[88]

Antibiotic therapy, aggressive surgical debridement including fasciotomy, and supportive care are the

Antibiotic therapy, aggressive surgical debridement including fasciotomy, and supportive care are the hallmarks of successful treatment.[88] With most clostridial infections penicillin is the drug of choice. In horses, penicillin is used at a dosage of 44,000 U/kg IV every 2 to 4 hours until the animal is stable (1 to 5 days). The intravenous dose is then reduced to four times a day or is replaced by oral metronidazole (15 mg/kg three or four times daily). In ruminants, similar intravenous or intramuscular drug therapy is indicated. In all cases, prolonged antimicrobial therapy may be necessary.

Surgical intervention at the affected site by means of debridement or fenestration in an attempt to reduce tissue swelling, aerate the tissues, and remove necrotic tissue is considered imperative for survival in horses (see Fig. 42-7). Incisions are made through the skin and into the affected muscle to establish adequate drainage and, it is hoped, alter the anaerobic conditions. Sufficient fenestrations should be made to establish drainage and aeration over the entire affected area.

Use of specific antitoxins is recommended when possible. However, these are often not available or not used for immediate therapy because the exact species of *Clostridium* causing the myonecrosis is not known. Cost considerations may also preclude their use.

Supportive fluid therapy and use of analgesics and antiinflammatory agents for control of pain and swelling are recommended. Short-acting corticosteroids such as dexamethasone, prednisolone, or hydrocortisone may be used for initial therapy of systemic and toxic shock, but continued use is contraindicated in the face of overwhelming sepsis.

1401

1402

If required, specific therapy should also be directed toward any other underlying problems.

42.7.1.1.7

Prognosis

The prognosis for life in all cases of clostridial myonecrosis is guarded to poor. The disease process is often rapidly fulminant, making treatment unrewarding. However, some animals have survived because of early diagnosis, aggressive therapy, and long-term supportive care. This is particularly true in cases involving *C. perfringens* in horses. The owner should be aware from the start of treatment that extensive skin sloughing may involve most of a limb and may force euthanasia to become a consideration at a later stage.

42.7.1.1.8

Prevention

Protection against clostridial myonecrosis is based on immunization procedures. Although clostridial agents are ubiquitous in the environment and frequently appear in the body of susceptible animals, rarely does adequate natural protection occur, although some colostral and acquired immunity may at times occur. Infection in unprotected animals usually follows a rapid, degenerative clinical course and terminates before the animal is able to generate an appropriate protective immune response. At present, only ruminants are commonly vaccinated against the agents responsible for clostridial myonecrosis. Vaccines used include multivalent bacterin toxoids containing antigens against two or more clostridial species, including *C. chauvoei, C. septicum, C. novyi, C. sordelli,* and *C. perfringens*. A rational program for protection usually involves vaccinating at an early age to establish immunity. Vaccination age is partly determined by other management factors, including when calves are handled for branding and castration, but 4 to 6 months of age is the usual time of initial vaccination. In areas of heavy exposure it may be necessary to vaccinate at 3 months and again at 4 months. In all clostridial species except *C. chauvoei,* two doses of vaccine are necessary to establish good protection. The duration of immunity is not long, and booster vaccinations should be administered every 6 to 8 months if protection is to be maintained. In many

booster vaccinations should be administered every 6 to 8 months if protection is to be maintained. In many herds it is necessary to vaccinate only animals under 3 years of age (i.e., those animals that are at greatest risk), but in some high-risk herds it is necessary to maintain a vaccination program for the life of the animal.

Animals that die of clostridial diseases should be disposed of by deep burial, burning, or removal from the premises to avoid further contamination of the environment.

42.7.2 RHABDOMYOLYSIS ASSOCIATED WITH *STREPTOCOCCUS EQUI*

STEPHANIE J. VALBERG

42.7.2.1 Acute Rhabdomyolysis

Severe acute generalized rhabdomyolysis has been reported to occur in quarter horses less than 7 years of age.[93,94] Affected horses have evidence of submandibular lymphadenopathy and/or guttural pouch empyema caused by *S. equi*. Horses develop a stiff gait that progresses rapidly to markedly firm, swollen, painful epaxial and gluteal muscles. In the majority of reported cases, animals became recumbent and unable to rise, and develop unrelenting pain necessitating euthanasia within 24 to 48 hours of hospitalization (Fig. 42-8). Hematologic abnormalities include mature neutrophilia, hyperfibrinogenemia, and marked elevations in CK (115,000 to 587,000 U/L), and AST levels (600 to 14,500 U/L). Titers to the M protein of *S. equi* are low in affected horses, unless horses are recently vaccinated for strangles. Titers to another protein called *myosin binding protein* were found to be high in a small number of horses that were tested.[93]

Fig. 42-8 A horse in severe pain and unable to rise because of acute rhabdomyolysis concurrent with guttural pouch empyema from *Streptococcus equi*.

At postmortem examination large, pale areas of necrotic muscle are evident in hindlimb and lumbar muscles. The histopathologic lesions are characterized by severe acute myonecrosis with a degree of macrophage infiltration. Sublumbar muscles often show the most severe and chronic necrosis, as indicated by greater

infiltration. Substantial muscles often show the most severe and chronic necrosis, as indicated by greater macrophage infiltration of myofibers.

Two causes have been proposed. The first possibility is a toxic shock—like reaction arising from profound nonspecific T cell stimulation by streptococcal superantigens with the release of high levels of inflammatory cytokines. An alternative explanation for rhabdomyolysis may be a bacteremia with local multiplication and production of exotoxins or proteases within skeletal muscle. *S. equi* virulence factors that may account for muscle necrosis include an unidentified cytotoxic protein, several proteases, streptokinase, and streptolysin S.[95] Although, *S. equi* has not been cultured in skeletal muscle from horses with rhabdomyolysis, *S. equi* bacteria have been identified in affected muscle using immunofluorescent stains for both Lancefield group C carbohydrate and *S. equi* M protein.[93] There is currently no evidence that the *S. equi* involved is an atypical genetic strain of *S. equi*.[96]

A high mortality rate has been reported in horses receiving intravenous penicillin therapy once clinical signs of strangles and myopathy were well established. It is possible that early recognition of the signs of muscle stiffness in horses with *S. equi* infections and prompt aggressive treatment may be required for a successful outcome. Although streptococcal species are exquisitely susceptible to β-lactam antibiotics, a mortality rate of 85% has been reported in human group A streptococcal myositis despite penicillin treatment.[97] An antimicrobial that inhibits protein synthesis, such as rifampin, combined with intravenous penicillin might enhance survival rates in horses with *S. equi* rhabdomyolysis. In addition, flushing infected guttural pouches and draining abscessed lymph nodes will diminish the bacterial load. Nonsteroidal antiinflammatory drugs (NSAIDs) and possibly high doses of short-acting corticosteroids may assist in diminishing the inflammatory response. Control of unrelenting pain is a major challenge in horses with severe rhabdomyolysis. Constant rate infusion of lidocaine, detomidine, or ketamine may provide better anxiety and pain relief than periodic injections of tranquilizers. Horses should be placed in a deeply bedded stall and moved from side to side every 4 hours if they are unable to rise. Some horses may benefit from a sling if they will bear weight on their hindlimbs when assisted to stand.

1402
1403

42.7.2.2

Infarctive Purpura Hemorrhagica

STEPHANIE J. VALBERG

Infarctive purpura hemorrhagica (IPH) is a severe form of purpura with a high fatality rate. In one study, prevalence of IPH was 3 of 53 cases of purpura.[98] Exposure to *S. equi* within 3 weeks of presentation, vaccination for *S. equi,* and a concurrent *Salmonella infantum* infection are reported inciting causes. Titers for serum enzyme-linked immunosorbent assay (ELISA) M protein may be markedly elevated.[99] The primary presenting complaint is often painful lameness with limb swelling, muscle stiffness, and/or colic. Careful physical examination reveals classic signs of purpura hemorrhagica such as petechia, oral infarctions resembling ulcers, and moderate well-demarcated limb edema; however, in addition, horses with IPH have focal firm intramuscular swellings (Fig. 42-9). Horses with evidence of colic may have markedly decreased borborygmi and hemorrhagic gastric reflux.

Hematologic abnormalities include a leukocytosis characterized by a neutrophilia with a left shift and toxic change, hyperproteinemia, hypoalbuminemia, and marked elevations in CK (47,000 to 280,000 U/L) and AST (960 to 7000 U/L) levels.[94,99] Peritoneal fluid obtained by abdominocentesis may be normal or may have an increased total protein, nucleated cell count, and RBC count if gastrointestinal infarction is present. Ultrasonographic examination of swollen muscle reveals focal hypoechoic lesions within muscle tissue.

Biopsies of abnormal muscle show diffuse acute coagulative necrosis, whereas samples from palpably normal muscle tissue show no pathologic abnormalities.

Fig. 42-9 Marked swelling of the left adductor muscles of the thigh caused by infarctive purpura hemorrhagica.

Fig. 42-10 Numerous infarctions of skeletal muscle caused by infarctive purpura hemorrhagica. (Photo courtesy of Dr. Beth Davis.)

Postmortem findings of horses with IPH include infarction of the skeletal musculature (Fig. 42-10), skin, gastrointestinal tract, pancreas, and lungs and *S. equi* abscessation of a lymph node. Definitive histopathologic findings include leukocytoclastic vasculitis and acute coagulative necrosis resembling infarction in numerous tissues.[99] IPH resembles Henoch-Schönlein purpura in humans, which is characterized by infarctive vasculitis of the skin, kidneys, and gastrointestinal tract resulting from IgA immune complex deposition. Immune complexes are present in the sera of horses with PH that appear to primarily be composed of IgM or IgA and streptococcal M protein.[100] Deposition of complement near immune complexes in vessel walls may result in cell membrane destruction, cell death, and vascular occlusion. The distinctive feature of IPH in horses is the extensive infarction of skeletal muscle and consequently marked elevation in serum CK and AST activity.

Early recognition of signs and aggressive antibiotic and corticosteroid treatment are essential to combat the high fatality rate with IHP. Treatment of Henoch-Schönlein purpura in humans, including cases with intestinal infarctions, involves high-dose intravenous pulse therapy with methylprednisolone followed by oral

corticosteroids plus immunosuppressive agents such as cyclophosphamide and azathioprine. One horse with IPH was successfully treated with penicillin, NSAIDs, and 3 weeks of dexamethasone (0.1 to 0.07 mg/kg) followed by a 10-week tapering course of oral prednisolone (2 mg/kg initially).[99]

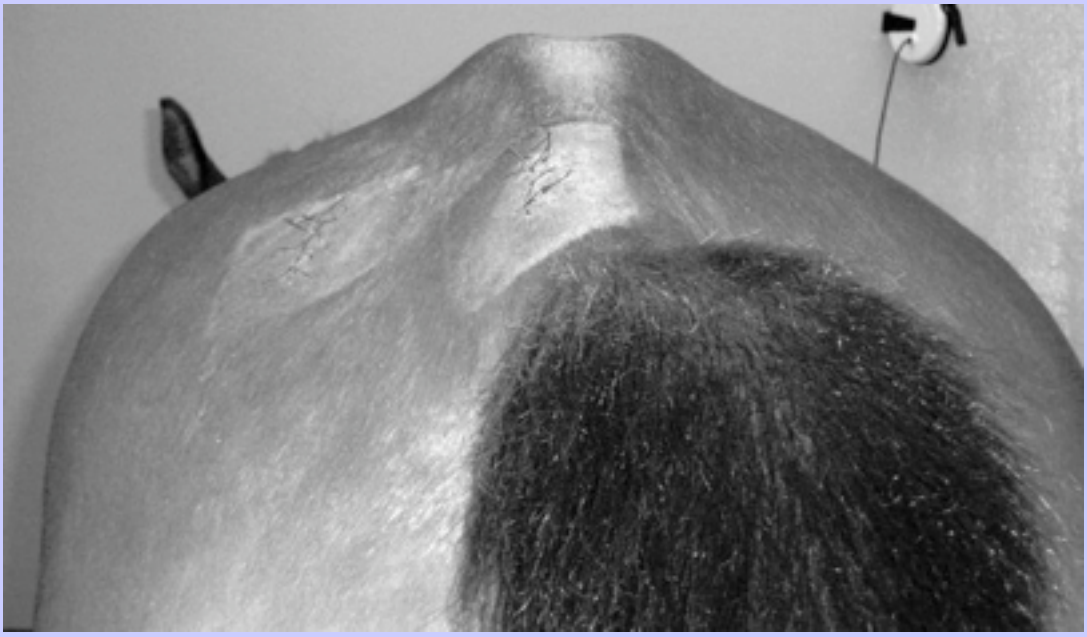
42.7.2.3 Immune-Mediated Polymyositis

STEPHANIE J. VALBERG

Immune-mediated polymyositis (IMM) has recently been reported in horses.[33,101,102] The majority of horses are of quarter horse bloodlines and are either ≤8 years of age or ≥16 years of age. In approximately one third of horses with IMM, a triggering factor appears to have been exposure to *S. equi* or a respiratory disease. The most prominent clinical sign of IMM in quarter horses is rapid onset of muscle atrophy, particularly affecting the back and croup muscles (Fig. 42-11), accompanied by stiffness and malaise. Atrophy may progress to involve 50% of the horses' muscle mass within a week and may lead to generalized weakness. Focal symmetric atrophy of cervical muscles has been reported in a pony with IMM.

1403 1404

Fig. 42-11 Symmetric atrophy of the gluteal muscles with immune-mediated myositis. (Photo courtesy of Dr. Beth Davis.)



Hematologic abnormalities are relatively minor in affected horses and are usually restricted to mild to moderate elevations in serum CK and AST activity. However, in some cases serum muscle enzyme activities are normal. Muscle biopsy of epaxial and gluteal muscles shows lymphocyte vasculitis, anguloid atrophy, lymphocyte myofiber infiltration, fiber necrosis with macrophage infiltration and regeneration. Biopsies of semitendinosus or membranous muscles may show some evidence of atrophy and vasculitis, but significant inflammatory infiltrates may be absent in these tissues. The extent of the inflammatory infiltrates in epaxial muscles is such that a diagnosis can often be established from several formalin-fixed Tru-Cut samples.

The lymphocytic infiltrate seen in muscle samples from horses with IMM contains a high CD4:CD8 ratio with no evidence of immunoglobulin G (IgG) binding to myofibers.[33] The reason why specific muscle groups are affected in horses with IMM is unclear.

Horses with concurrent evidence of streptococcal infection should be treated with antibiotics. It is likely prudent to avoid intramuscular injections. Administration of corticosteroids appears to immediately improve signs of malaise and inappetence and prevented further progression of muscle atrophy. Recommended dosages are dexamethasone 0.05 mg/kg for 3 days, followed by prednisolone 1 mg/kg for 7 to 10 days tapered by 100 mg/week over 1 month. Serum CK activity often normalizes after 7 to 10 days. Muscle mass usually gradually recovers over 2 to 3 months. Horses that are not treated with corticosteroids may develop extensive muscle atrophy, but in many cases muscle mass will gradually recover. Recurrence of atrophy in susceptible horses is common and may require reintroduction of corticosteroid therapy. Some horses develop focal residual muscle atrophy.

42.7.3 VIRUS-ASSOCIATED MYOPATHY

STEVEN M. PARISH

Necrosis of skeletal and cardiac muscle occurs frequently in association with some viral diseases. In most situations, viral-induced muscle damage represents a component of systemic multiple organ system involvement. For example, myocarditis occurs in association with foot-and-mouth disease, equine influenza, and equine infectious anemia. Other diseases that cause myocarditis or skeletal muscle manifestations include bovine ephemeral fever, malignant catarrhal fever, bovine virus diarrhea, and bluetongue. Equine influenza A2 and equine herpesvirus 1 have been reported to induce primary muscle stiffness and clinical signs resembling those seen in horses with rhabdomyolysis.[103,104] Details concerning specific clinical manifestations can be found in other sections of this text.

42.7.4 SARCOCYSTOSIS

STEVEN M. PARISH

STEPHANIE J. VALBERG

Cysts of the sporozoan parasite *Sarcocystis* are commonly seen in routine histologic sections of the heart, esophageal, and skeletal muscle of cattle, sheep, goats, and horses.[105–108] More than 90% of horses over 8 years of age have sarcocysts in their esophageal muscles. Cysts may pose no problem, but with heavy infestations multisystemic dysfunction occurs.[105,109–111] Experimentally induced acute disease is characterized by fever, mild anemia, chronic myositis, and muscle wasting.

42.7.4.1 Epidemiology

The life cycle of the parasite involves two hosts: carnivores as the definitive host and cattle or horses as the intermediate host. Three species of sarcocysts, *Sarcocystis cruzi, Sarcocystis hirsuta,* and *Sarcocystis hominis,* are known to infect cattle; canids, felids, and primates are the definitive hosts for these species. Three sarcocyst species have been described in horse muscle: *Sarcocystis bertrami, Sarcocystis equicanis,* and *Sarcocystis fayeri*. Dogs have been identified as the definitive host for these equine sarcocyst species. In sheep and goats, *Sarcocystis ovicanis* and *Sarcocystis arieticanis* have been described, with canids as the

sheep and goats, *Sarcocystis ovicanis* and *Sarcocystis capracanis* have been described, with canids as the definitive host.

The most common mechanism for natural infection in cattle is by ingestion of feeds contaminated with infected carnivore feces. Feedlot workers using feed bunks as toilets may be a source of exposure for feedlot cattle.

42.7.4.1.1

Clinical Signs

Although low-level natural infection is common in cattle, when administered experimentally a dose of 200,000 sporocysts of *S. cruzi* is necessary to cause severe clinical disease.[105] Within 4 weeks the animal develops fever (39.4° C [103° F]), anorexia, salivation, weight loss, weakness, muscle fasciculations, severe depression, and sometimes death. Fever is the earliest sign and is biphasic relative to two periods of parasitemia, one occurring at 15 to 19 days and another at 25 to 42 days after inoculation. During the second febrile episode, affected calves frequently develop other clinical signs, particularly anemia. Extravascular hemolysis occurs, and hemorrhage into many tissues is common. The mechanisms involved in the hemolytic and hemorrhagic phases are likely to involve immune mechanisms. Mortality is greatest during this phase of the disease. Laboratory analysis may reveal elevations in serum urea nitrogen and bilirubin concentrations, sorbitol dehydrogenase, LDH, CK, and AST activity. If animals survive, these laboratory values usually return to normal in approximately 2 weeks. Animals surviving this phase commonly continue to be inappetent and have decreased weight gains; muscle atrophy; and hair loss on the neck, rump, and tail. These changes are mediated by alterations in a variety of pathways, the net result being a partitioning away of nutrients that are used for growth.[112] The anemia is ameliorated by a regenerative process, with normal hematologic values obtained in 1 to 2 months after clinical recovery. Similar clinical findings are seen in sheep and goats. Abortion is common. A syndrome similar to that described in cattle has been reported in two horses with malaise, fever, and muscle atrophy.[108,113]

1404

1405

Diagnosis of sarcocystosis requires history, clinical signs, laboratory and serologic evaluation, and the demonstration of immature cysts in muscle biopsies. It is important to differentiate between the muscle cysts caused by *Sarcocystis* and those produced by toxoplasmosis because toxoplasmosis does not cause clinical disease in cattle.

42.7.4.1.2

Treatment

Specific treatment is effective only in the early stages of sarcocystosis in food animals. Experimental therapy with amprolium or the ionophore antibiotics before the second stage of parasitemia frequently prevents development of clinical sarcocystosis in cattle.[114] Successful treatment of one horse with sarcocystosis using phenylbutazone, trimethoprim-sulfa, and pyrimethamine is reported.[113]

Control involves preventing gross contamination of cattle and equine feeds with carnivore feces. The common use of ionophore antibiotics (e.g., growth promotants and coccidiostats) in cattle is also likely to help reduce the incidence of sarcocystosis.

42.7.4.2

NUTRITIONAL AND TOXIC RHABDOMYOLYSIS

42.7.4.2.1

Nutritional Myodegeneration

JOHN MAAS

STEPHANIE J. VALBERG

42.7.4.2.1.1

Definition and Etiology

Nutritional myodegeneration (NMD; white muscle disease, stiff lamb disease, nutritional muscular dystrophy) is a peracute to subacute myodegenerative disease of cardiac and skeletal muscle caused by a dietary deficiency of selenium or vitamin E.[115–118] This syndrome occurs in most farm animal species but is most commonly found in young, rapidly growing calves, lambs, kids, and foals, particularly those born to dams that consumed selenium-deficient diets during gestation. The disease has also been reported in yearling and adult cattle and has been suspected in adult horses.

Selenium and vitamin E appear to be synergistic in preventing NMD. However, on the basis of prophylaxis and response to treatment, selenium deficiency appears to be more important.

42.7.4.2.1.2

Clinical Signs

There are two distinct syndromes of NMD: a cardiac form and a skeletal form. The cardiac form is associated with signs of peracute to acute myocardial decompensation, but the skeletal form is associated with skeletal myasthenia and difficulty in ambulation. In both forms the most rapidly growing animals in the herd or flock are affected commonly.

Most cases of NMD are diagnosed during the first year of life. Evidence also suggests that an in utero form of NMD may occur, with affected animals born with myodegeneration or developing myodegeneration soon after birth.

The cardiac form of NMD usually has a sudden onset; it is usually diagnosed in the animal that is either in a state of severe debilitation or dead. The cardiac form often manifests with lesions in the heart, diaphragm, and intercostal muscles. In dead animals there may be evidence of sudden agonal death. In living animals there is usually a rapid onset of depression and respiratory distress. A foamy nasal discharge, possibly bloodstained, is seen often, resulting from pulmonary edema and dyspnea. Profound weakness, recumbency, and a rapid, often irregular heartbeat may be detected. Cardiac murmurs are heard occasionally on auscultation. Rectal temperature is normal usually or may be elevated because of increased muscular work associated with respiratory efforts. Most calves are depressed, with dyspnea, tachypnea, and increased rectal temperature. These cases must be differentiated from pneumonia. The clinical course is frequently short, with death occurring commonly in less than 24 hours despite medical therapy. Occasionally an animal responds to therapy, but such animals often fail to thrive because of residual myocardial damage. Animals with predominantly cardiac signs may also manifest mild skeletal muscle problems associated with NMD.

The skeletal form of NMD frequently has a slower onset characterized by muscular weakness or stiffness. Animals may be recumbent and unable to stand. Those that are able to rise on their own or with assistance show muscle weakness, trembling of limb muscles, or stiffness. Stiffness is more

with assistance show muscle weakness, trembling of limb muscles, or stiffness. Stiffness is more pronounced as fibrosis occurs after an acute attack. Most affected animals are able to remain standing only for short periods. Supporting muscle groups of the frontlimbs and hindlimbs may appear swollen and may be hard and painful on palpation. Commonly affected muscle groups may include the gastrocnemius, semitendinosus, semimembranosus, and biceps femoris and muscles of the lumbar, gluteal, and neck regions. If the diaphragm and intercostal muscles are affected, the animal may show respiratory distress and evidence of increased abdominal effort when breathing. Cardiomyopathy occurs often, along with changes in the diaphragm and intercostal muscles. The muscles of the tongue may be involved, resulting in dysphagia. Dysphagia may be the only sign in some affected animals; foals and lambs are presented in this condition more often than calves. The rectal temperature is normal or moderately elevated, resulting from pain and the release of myoglobin associated with myodegeneration. Some animals exhibit what appears to be abdominal pain with violent thrashing. Heart sounds are normal usually, although the heart rate may be increased; however, myocardial damage and signs consistent with cardiac dysfunction may be present in cases of skeletal NMD. Animals with skeletal NMD often respond favorably to treatment and rest. Improvement is evident after a few days, and within 3 to 5 days animals can often stand and walk.

Differentiation of NMD from other diseases causing sudden death or recumbency is important. Infectious diseases resulting in septicemia, pneumonia, and toxemia may have similar presenting signs. Acute heart failure resulting from cardiac anomalies, cardiotoxic agents such as those found in plants (oleander, cassia, yew, white snakeroot, and gossypol toxicity from cottonseed), and the ionophore antibiotics should also be considered. Other diseases that cause stiffness of gait, weakness, and recumbency with no change in mental status must be differentiated from NMD. Spinal cord compression, cerebellar disease, suppurative and nonsuppurative meningitis or myelitis, polyarthritis, neurotoxins such as organophosphates, tetanus, pelvic fractures, and parasitic myositis all can cause recumbency. Clostridial myositis and traumatic injuries to muscles, long bones, and joints should be considered. Diseases characterized by abdominal pain may resemble NMD, because they may also cause stiffness of gait, weakness, and recumbency.

42.7.4.2.1.3

Clinical Pathology

Significantly elevated CK, AST, and LDH activities occur during the acute phase of myodegeneration. In clinical cases CK levels are in the thousands of international units per liter. In animals recumbent because of a disease other than NMD, CK is elevated only into hundreds of or perhaps a few thousand international units per liter in heavy animals. Progressively decreasing activities of CK can be used as a prognostic indicator of a reduction in the myodegenerative process.

1405 1406

In foals, other reported abnormal laboratory findings include variable hyperkalemia, hyperphosphatemia, hyponatremia, and hypochloremia.[118] Myoglobinuria is found often in foals and yearling cattle with NMD. Myoglobinuria is less common in younger calves. Evidence of dehydration, reflected by elevated serum protein concentrations and hemoconcentration, is common in nonambulatory animals unable to nurse or drink water.

The selenium status of an animal or members of a group can be determined by laboratory analysis of tissue biopsies and whole blood (Table 42-2). Vitamin E status can be determined on serum or plasma samples. In the clinical setting, blood samples are more frequently used. Blood or plasma samples provide information about the circulating levels of selenium and vitamin E, respectively, and are satisfactory for assessing intermediate to long-term nutritional status; however, short-term supplementation or injections can confuse interpretation of circulating levels of selenium or vitamin E

supplementation or injections can confuse interpretation of circulating levels of selenium or vitamin E. Tissue biopsies and tissue specimens obtained at slaughter and necropsy provide an indication of storage and can also be used to assess herd status and success of supplementation. Whole blood selenium analysis is preferred over plasma and serum.[119] Whole blood selenium concentrations ranging from 0.07 to greater than 0.1 ppm (µg/g) are considered normal in large animals. Normal liver concentrations of selenium are 0.9 to 1.75 µg/g of dry matter (DM), 0.9 to 3.5 µg/g DM, and 1.05 to 3.5 µg/g DM for cattle, sheep, and horses, respectively.[120] Selenium-dependent glutathione peroxidase (GSH-Px) formed in the red cells during erythropoiesis also provides an index of body selenium status. Cross-reacting enzymes, such as glutathione reductase, are not found in erythrocytes. Adequate GSH-Px activities are greater than 30 U/mg of hemoglobin per minute in cattle, 60 to 180 U/mg of hemoglobin per minute in sheep, and 20 to 50 U/mg of hemoglobin per minute in horses. However, GSH-Px reference values are specific only to the laboratory where the analysis is performed and must be validated by comparison with blood selenium concentration. The activity of GSH-Px in RBCs of domestic species remains constant for 4 to 6 days when maintained at 39° F (4° C); after this time significant decreases occur. The critical concentration of vitamin E (α-tocopherol) in plasma is 1.1 to 2 ppm (µg/g) in large animals. Vitamin E deteriorates rapidly in plasma samples. Therefore plasma samples for α-tocopherol analysis need to be put on ice immediately, protected from the light by wrapping in tin foil, and stored (–21° F [–70° C]) if analysis is to be delayed.

Table 42-2 Deficient, Marginal, and Normal Concentrations of Whole Blood Selenium and Glutathione Peroxidase Activities in Sheep and Cattle [67,71]

Whole Blood Selenium (ppm)*	GSH-Px (U/mg Hb/min)	Category	Interpretation
0.01-0.04	0-15	Deficient	Selenium supplementation is always beneficial.
0.05-0.06	15-25	Marginal	Selenium supplementation is often beneficial.
0.07	25-500	Normal	Selenium supplementation is never beneficial.
GSH-Px assays are performed by different procedures in individual laboratories, and quantitative relationships between blood selenium concentrations and blood GSH-Px activities can vary. These numeric relationships are site-specific, and interpretation must account for these differences.			

* *GSH-Px,* Glutathione peroxidase; *PPM,* parts per million.

42.7.4.2.1.4

Pathophysiology

The effects of selenium and vitamin E deficiency have been postulated to result, at least in part, from the destruction of cell membranes and proteins leading to a loss of cellular integrity.[115,121] Selenium, which has been shown to be an essential component of at least five selenoproteins[122] (three glutathione peroxidase enzymes, a deiodinase in liver and kidney that converts T_4 to T_3, and selenoprotein-P, a plasma protein of unknown function), and vitamin E (α-tocopherol) serve as biologic antioxidants. During normal cellular metabolism highly reactive forms of oxygen (free radicals) are produced. These include hydrogen peroxide, hydroperoxides, lipoperoxides, superoxide, various hydroxy radicals, and singlet oxygen. Vitamin E is active within the cell membrane as a lipid-soluble antioxidant that scavenges free radicals that otherwise might react with unsaturated fatty acids to form lipid hydroperoxides. In contrast, GSH-Px destroys hydrogen peroxide and lipoperoxides that have already been formed and converts them to H_2O or relatively harmless alcohols. Other enzymes such as catalase and superoxide dismutase are also involved in this protective process.

Apparently important interrelationships exist among the selenium and vitamin E status of the animal, the level of polyunsaturated fatty acids (PUFAs) in the diet,[115,121] and NMD, particularly in ruminants.[115] PUFAs of dietary origin can undergo peroxidation to hydroperoxides, forming toxic free radicals. During active growing periods pasture grasses and plants contain high concentrations of linolenic acid, a PUFA. Under normal conditions the rumen is thought to be important in saturating dietary unsaturated fatty acids. However, concentrations of PUFAs in the plasma often increase in calves recently turned out to pasture, possibly enhancing the chance of free radical formation and tissue damage. This indicates that the capacity of the various protective mechanisms can be overwhelmed by dietary factors such as high levels of PUFAs. It is not surprising that selenium- or vitamin E—deficient animals may be at a greatly increased risk of tissue oxidative damage when exposed to such diets. However, the potential for induction of NMD by this process should not be overemphasized, because calves on a milk diet may be severely affected.

The precise interrelationships among selenium, vitamin E, other metabolic factors, and triggering mechanisms in NMD are not fully understood because many animals deficient in selenium or vitamin E have no evidence of muscle disease. In certain situations deficiencies of both selenium and vitamin E are necessary for disease to occur. In other animals NMD can occur when a deficiency of only one of the agents is present and levels of the other are normal in blood and tissues.

42.7.4.2.1.5

Epidemiology

NMD occurs in all farm animals and is seen most commonly in young, rapidly growing calves, lambs, kids, and foals. The occurrence of NMD in very young animals usually reflects a deficiency in their dams during a substantial portion, if not all, of the gestation period. The selenium and GSH-Px values of neonatal calves tend to be similar to those of their dams.[123,124]

Marginally to severely selenium-deficient areas occur throughout a large portion of the United States and other countries of the world.[115,125] Forages and grains produced in the northeastern and eastern seaboards and northwestern regions of the United States are particularly deficient because of low soil levels of selenium. Acid soils and those originating from igneous (volcanic) rock are often selenium deficient, as are those having high sulfur content or soils treated with sulfur-containing fertilizers. Sulfur inhibits selenium uptake by plants and absorption by animals. Different forages in a specific area will also vary in their selenium content. Legumes take up less selenium than do grasses. Also, forage selenium concentrations are lowest during periods of rapid growth such as in the spring and during

1406
1407

selenium concentrations are lowest during periods of rapid growth such as in the spring and during times of highest rainfall.

Vitamin E deficiency occurs most commonly when animals are fed poor-quality hay, straw, or root crops. Grain treated with propionic acid and having high moisture content is commonly vitamin E deficient. Storage of grain crops for extended periods results in marked decreases in their vitamin E content. Calves fed milk replacers that contain fish oil, linseed oil, soybean oil, or corn oil, all of which increase the dietary levels of unsaturated fatty acids, require increased dietary supplementation of vitamin E to avoid deficiency. In contrast, cereal grains, green growing pastures, and properly prepared hay usually have adequate vitamin E.

In young ruminants the majority of cases of NMD occur in calves 2 to 4 months of age during the spring and summer months in association with exercise when at pasture, although congenital and perinatal cases do occur. Histologic lesions consistent with NMD have also been seen in late-term aborted fetuses.[120] These findings are suggestive of an in utero form of NMD in large animals. Yearling cattle housed during the winter, fed diets high in grain with high moisture content, and then turned out in the spring may also be affected. Lambs born in confinement and turned out to pasture at 1 to 3 weeks of age frequently develop signs of NMD. Stresses such as transport, herding, and driving may also precipitate signs of NMD. In horses, NMD generally occurs during the first year of life, with most cases observed from birth to weaning.[116,126]

42.7.4.2.1.6

Necropsy Findings

Bilaterally symmetric myodegeneration is a consistent finding in NMD. Skeletal muscle degeneration is characterized by pale discoloration and a dry appearance of affected muscle, white streaks in muscle bundles, calcification, and intramuscular edema (Fig. 42-12). The white streaks seen in muscle bundles represent bands of coagulation necrosis or, in chronic cases in which insults may have occurred weeks before, may represent fibrosis and calcification. Affected muscle bundles are often adjacent to apparently normal or minimally affected muscle. The color of normal muscle in young calves is pale because of reduced myoglobin concentrations; therefore close inspection and histologic examination are necessary in cases of suspected NMD. Cardiac muscle undergoes changes similar to those of skeletal muscle. In calves the left ventricle and septum are most frequently involved (Fig. 42-13), but in lambs both ventricles are usually involved. Myocardial degeneration usually extends through the full thickness of the ventricular wall.

Histologically, affected muscle fibers may be hypercontracted and fragmented with some mineralization of muscle fibers and others undergoing macrophage infiltration. In yearling cattle, type I muscle cells are more frequently affected.

42.7.4.2.1.7

Treatment and Prognosis

In the cardiac form of NMD myocardial damage is often extensive and incompatible with life. Only rarely is treatment successful. In contrast, the skeletal form of NMD is more generally amenable to treatment, although the prognosis for clinical recovery from the skeletal form of NMD is guarded and often depends on whether secondary complications such as respiratory disease develop. In all cases of NMD, therapy should involve specific supplementation with selenium and vitamin E and general supportive care.

Fig. 42-12 White streaks within diffusely pale skeletal muscle caused by nutritional myodegeneration.

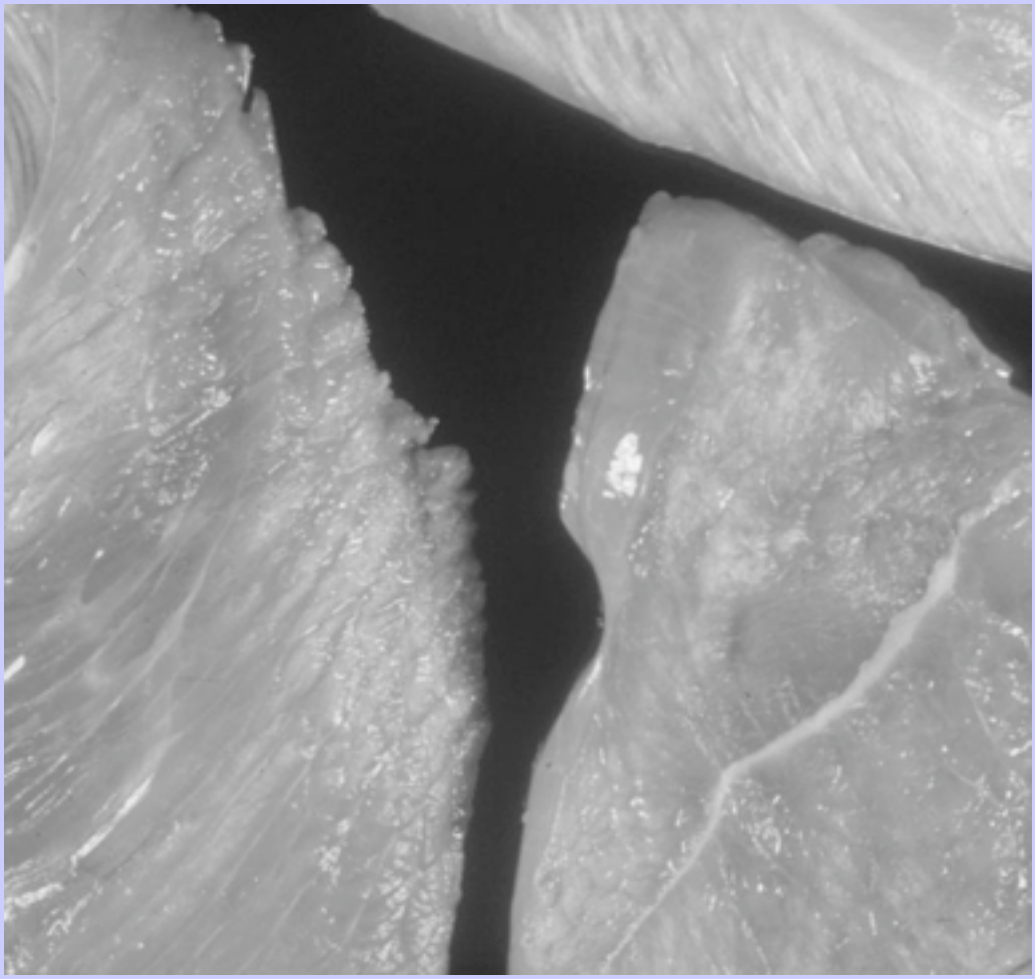


Fig. 42-13 Pale areas of muscle necrosis in the myocardium of a calf with nutritional myodegeneration.

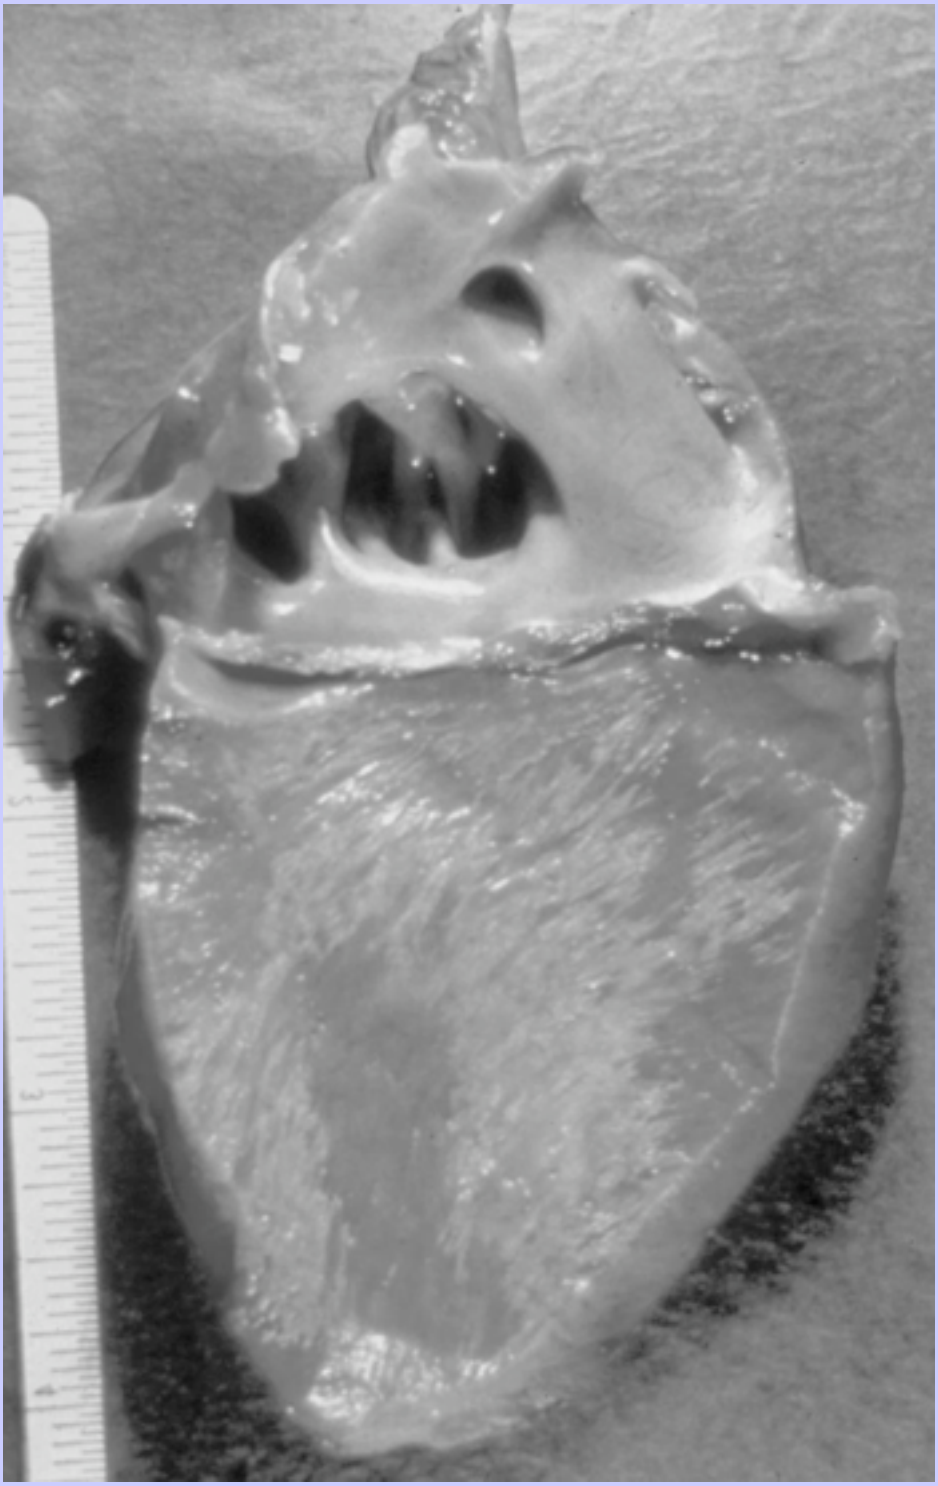

Alleviation of selenium-responsive NMD requires the use of injectable selenium products. These are available with selenium concentrations varying from 1 mg of selenium per milliliter to 5 mg/mL, with all products containing 50 mg/mL (68 IU) of vitamin E as DL-α-tocopheryl acetate. The label dose for

all products containing 50 mg/mL (50 IU) of vitamin E as DL-α-tocopheryl acetate. The label dose for selenium is 0.055 to 0.067 mg/kg (2.5 to 3 mg/45 kg) of body weight given intramuscularly or subcutaneously. Dosage of these injectable products should not be greatly increased above the label dosage to prevent an inadvertent selenium toxicosis. However, when using the vitamin E and selenium combinations, the amount of vitamin E in these combination products is present as a preservative for the solution and is therefore insufficient for vitamin E supplementation. Injectable vitamin E products are now available that contain 300 IU of vitamin E per milliliter as D-α-tocopherol* and 500 IU of vitamin E per milliliter as D-α-tocopherol.† Administration of these products increases the tissue and/or plasma level of vitamin E activity for approximately 3 weeks in farm animals. The bioavailability of vitamin E from injectable products is dependent on the form of vitamin E (the alcohol form, D-α-tocopherol, being the most active) and the amount and quality of the solution emulsifier used. Bioavailability data on injectable vitamin E products should receive careful clinical consideration. Oral supplementation is the general approach to provide additional dietary levels of vitamin E. Recommended levels of supplementation for calves range from 15 to 60 mg of DL-α-tocopheryl acetate per kilogram of dry feed.[125] For horses a daily supplement of 600 to 1800 mg of DL-α-tocopheryl acetate has been recommended.[126] Oral α-tocopherol is now available for all species and contains 500 IU of vitamin E per milliliter.‡ The recommended dose of this product is 1 to 3 IU/lb of body weight. Studies with injectable selenium show that absorption and distribution occur rapidly.[127] It is thought that incorporation of selenium into heart, skeletal muscle, and other tissues may be very rapid and could account for the rapid improvement in clinical signs seen in reversible cases. The discovery of four new selenoproteins may help explain these clinical observations.[122] This improvement can occur even though blood GSH-Px activity rises slowly because of the delay caused by erythropoiesis and release of red cells from the bone marrow.[127] However, platelet GSH-Px activity rises within hours and may be a more accurate reflection of changes in muscle and other tissues.

Supportive therapy may include administration of antibiotics to help combat secondary pneumonia and infected decubital lesions that are common in recumbent patients. Provision of adequate energy intake and attention to the fluid and electrolyte balance are of critical importance if recovery is to be successful.

42.7.4.2.1.8

Prevention and Control

The prevention and control of NMD are achieved through supplementation of selenium and vitamin E. Although selenium deficiency is implicated more commonly in most NMD syndromes, attempts to ensure adequate provision of selenium and vitamin E should be undertaken. Under current U.S. federal regulations, selenium can be incorporated into the total ration of ruminants and other species to a level of 0.3 parts per million (ppm). In salt and mineral mixtures formulated for free-choice feeding, selenium can be incorporated at 90 ppm for sheep and 120 ppm for cattle. In certain areas or in herds, levels as high as 200 ppm selenium in salt and mineral mixtures may be necessary to maintain adequate selenium levels in the animals. Federal regulations limit the intake of supplemental selenium by sheep to 0.7 mg/head/day and by cattle to 3 mg/head/day. The use in ruminants of ruminoreticular boluses, which release a precise amount of selenium daily, has been commonplace in many countries of the world; however, under current U.S. Food and Drug Administration (FDA) guidelines these products are not available in the United States. These slow-release boluses can replace supplementation by salt mixtures or by

the United States. These slow-release boluses can replace supplementation by salt mixtures or by injections and are extremely valuable in extensive grazing systems. Alternatively, individual animals can be supplemented by periodic (30- to 60-day intervals) injections of selenium and vitamin E preparations to help maintain body concentrations and assist in transplacental transfer of selenium to the fetus.

Oral supplementation for horses at 1 mg of selenium per day increases blood selenium concentrations above levels known to be associated with NMD.[128] Supplementation of pregnant mares is advised in areas known to be selenium deficient; however, only limited selenium may cross the placenta.[117] Supplementation during lactation increases the levels of selenium in milk and thus provides a potential means of selenium supplementation in foals; however, evidence in cattle indicates that this increased level of selenium in milk may not meet nutrient requirements.[123–125]

Regardless of the method of supplementation, periodic blood (or tissue) sampling of animals at risk is recommended to ensure desired levels of selenium. In high-risk areas, samples should be taken every 60 to 90 days to determine selenium status in susceptible animals and every 6 to 12 months to monitor supplementation. On the basis of these assessments, adjustments to the rate or extent of selenium supplementation may be made.

Feeding animals properly prepared and stored hay and grain or allowing them access to high-quality green forage should ensure adequate vitamin E intake.

42.7.4.2.2

Toxic Causes of Rhabdomyolysis

MICHAEL MURPHY

STEPHANIE J. VALBERG

Ingestion of toxic substances in feed or forage is a common cause of toxic rhabdomyolysis.

42.7.4.2.2.1

Toxic Plants

Gossypol is of greatest significance in swine. Monogastrics, including young calves, should not ingest feed containing more than 200 ppm of gossypol. Mature ruminants may tolerate 20 g of gossypol per day. This normally amounts to 5 to 6 lb of whole cottonseed per head per day.[129] Two common forage toxins that cause myonecrosis are *Cassia* species and tremetone-containing plants. *Cassia obtusifolia* (sicklepod) is prevalent in the southeastern United States, and ingestion of seeds by swine, ruminants, or horses may cause a degenerative myopathy and cardiomyopathy with evidence of myofiber atrophy, segmental necrosis, and mitochondrial disruption.[130] White snakeroot *(Eupatorium rugosum)* grows in shaded areas of the eastern and central United States,[131] and rayless goldenrod *(Isocoma wrightii)* is common in the Southwest on open pastures. These tremetone-containing plants can cause a fatal cardiomyopathy and severe skeletal muscle degeneration in horses when ingested at 0.5% to 2% of body weight.[132,133] Other grazing livestock are likely to be affected by ingestion of these plants at 2% of body weight. Tremetone remains active in hay and in the stalks of the dead plants on pasture, so both the fresh and the dried form of the plants should be kept from livestock.[134] Microsomal activation of the toxin in the liver may be necessary for toxic effects.[132]

42.7.4.2.2.2

Atypical Myopathy

1408

1409

A highly fatal myopathy that occurs in large numbers of horses on pasture during cold wet conditions occurs in the fall in Europe and the midwestern United States.[135–139] Terms such as *atypical myopathy, atypical myoglobinuria,* and *pasture myopathy* have been used to describe this syndrome. Affected horses are usually kept on pasture for more than 12 hours per day without snow cover when minimum daily temperatures range from 29° F to 56° F and weather is often inclement. Clinical signs develop acutely and include muscular weakness, sweating, fasciculations, stiffness, tachycardia, tachypnea, recumbency, and, when urine is observed, myoglobinuria. The most notable change in serum biochemistry is a marked increase in serum CK and AST activity. Serum troponin I concentrations may be high, indicating cardiomyopathy. Postmortem findings include extensive necrosis in postural and respiratory muscles and, in 50% or more of cases, myocardium (Fig. 42-14). Serum vitamin and selenium as well as urine tremetone concentrations are normal. Frozen sections of myocardium, intercostal, diaphragm, or deep postural muscles show marked intracellular lipid accumulation in oxidative fibers (oil red O stain). A few horses have survived with aggressive fluid therapy, antioxidant, and antiinflammatory treatment including dimethyl sulfoxide (DMSO), vitamin E, vitamin C, and NSAIDs.[135] The cause of pasture myopathy is suspected to be an ingested or enterically produced toxin (e.g., bacterial toxin, mycotoxin, or phytotoxin that disrupts lipid metabolism).[138] Soil-borne ionophores or clostridial toxins have been suggested as possible causes.[139]

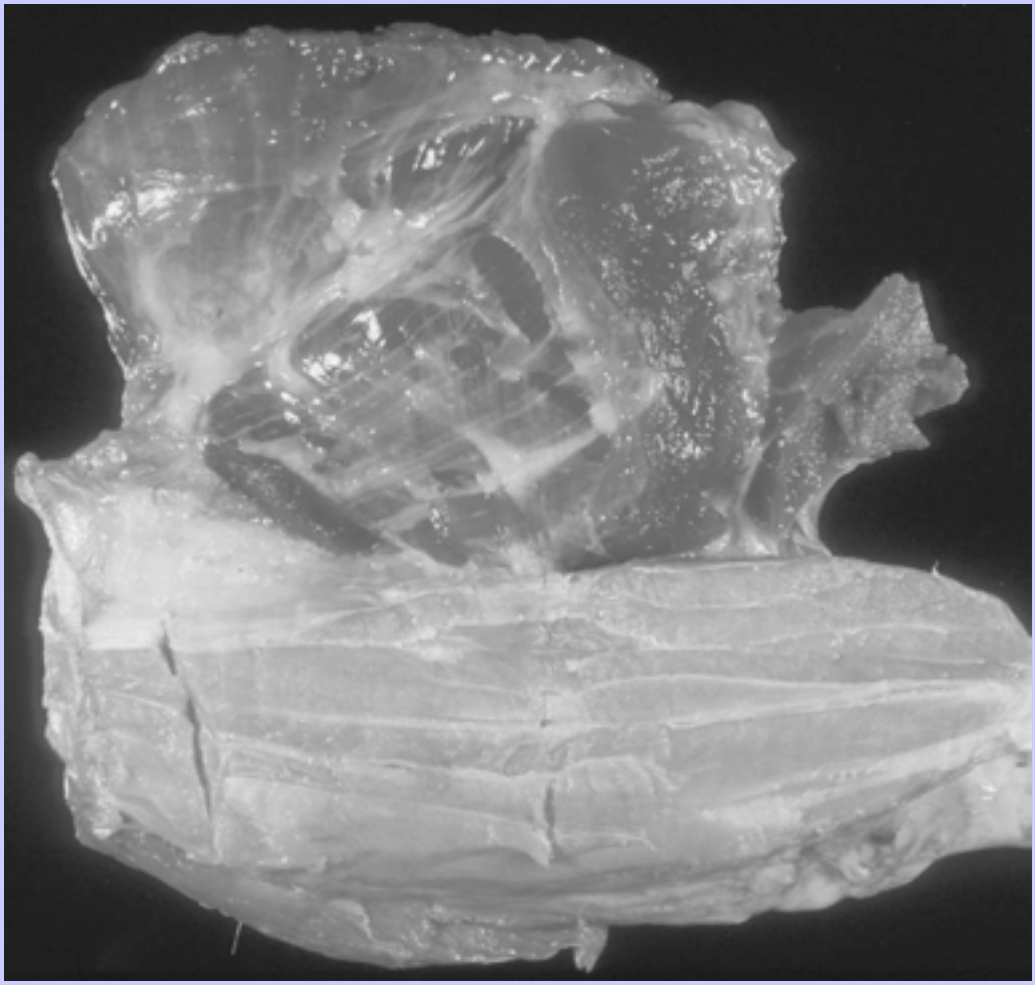
42.7.4.2.2.3

IONOPHORES

Ionophores are commonly added to feeds for their growth promotion and coccidiostat properties. Species differences in sensitivity to ionophores and the variety of ionophores on the market have led to several cases of ionophore-induced toxicosis. Rhabdomyolysis and cardiomyopathies are common sequelae to ionophore toxicosis. Experimental studies have indicated that LD_{50} values for monensin are 2 to 3, 12, 17, 26, and 21 to 36, for horses, sheep, pigs, goats, and cattle, respectively. Feed concentrations of 100 g/ton and 400 g/ton have been fatal to sheep and cattle, respectively.[129,140] Newborn calves given 100 mg of lasalocid three times daily for treatment of cryptosporidiosis experience muscle necrosis.[141] Other ionophores include naracin, salinomycin, and laidlomycin. Ionophores are quickly eliminated from the body after exposure.

Fig. 42-14 The lower muscle group shows severe compartmental muscle necrosis resulting in total pallor and friable muscle

tissue. In comparison the upper muscle group is normal in color and grossly unaffected.



42.7.4.2.2.4

CHEMICAL TOXINS

Several chemical agents have been associated with muscle necrosis on rare occasions. Parenteral products, insecticides, and feed contaminants have been implicated. Muscle necrosis has been reported in cattle and pigs that received injections of lidocaine, diazepam, digoxin, levamisole, nitroclofene, pentazocine, thiazinamium, chloramphenicol, and oxytetracycline and in horses after injectable ivermectin administration. One of 70 horses poisoned with blister beetles developed muscle necrosis.[87,142] Animals with organophosphate toxicosis, particularly from parathion, may develop muscle necrosis.[143–145] Several miniature horses being fed a complete feed containing tetrachlorvinphos, a feed-through fly control agent, were reported to develop chronic myonecrosis involving masseter, tongue, neck, respiratory muscles, and postural muscles and occasionally cardiac muscle.[146] Affected horses showed signs of lethargy, dysphagia, fasciculations, tachypnea, and tachycardia. Muscle tissue showed evidence of chronic myonecrosis as well as lipid accumulation. Myonecrosis was attributed to

acetylcholine accumulation at muscarinic and nicotinic sites, producing oxidant stress. Low selenium concentrations may contribute to the toxicosis.

42.7.4.3 TRAUMATIC RHABDOMYOLYSIS

42.7.4.3.1 Compartment, Downer, and Muscle Crush Syndrome of Cattle

DAVID R. HODGSON

STEPHANIE J. VALBERG

Muscle damage commonly accompanies the downer syndrome in large animals. The downer syndrome is discussed in greater detail in Chapter 41. Animals weakened by disorders such as hypocalcemia are more prone to tearing adductor or semitendinosus and membranosus muscles in attempts to rise.[32,147] Initial traumatic laceration of muscle leads to edema and inflammation, both of which may exacerbate local tissue degenerative changes. In addition, the weight of a recumbent animal on dependent muscle groups creates significant increases in intramuscular pressure, resulting in decreased perfusion and ischemia of muscle and nerve. Signs of weakness and peroneal or tibial nerve paralysis most commonly accompany this type of injury. Mild elevations in serum CK can be expected in cows that are recumbent, but elevations greater than 5000 U/L usually indicate traumatic muscle damage. Treatment requires correcting the underlying cause of recumbency, fluid therapy if renal damage is evident, NSAIDs, good nursing care, adequate footing and bedding, and lifting or rolling the animal several times a day. Aquatherapy using float tanks for cattle also appears to be beneficial in relieving the pressure on muscle groups.

42.7.4.3.2 Postanesthetic Myoneuropathy

Postanesthetic myoneuropathy is a condition that has become much more prevalent since the advent of inhalation general anesthesia. The disorder can be categorized as occurring in two forms: (1) localized myopathy-neuropathy, and (2) generalized myopathy somewhat similar to MH.

42.7.4.3.3 Localized Myopathy-Neuropathy

42.7.4.3.3.1 Clinical Signs

Localized myopathy usually occurs in muscles that are in contact with a hard surface during anesthesia or those in which arterial blood supply is compromised through positional occlusion. Commonly affected muscles include triceps, deltoid, masseter, hindlimb extensors, or, if the horse has been in dorsal recumbency, the hindlimb adductor and gluteal muscles.[148–150] Injury also may occur to nerves in these areas, resulting in temporary radial, peroneal, or femoral nerve paralysis (Fig. 42-15). Clinical signs may be apparent on recovery or may be delayed for periods of up to 30 to 60 minutes after the horse has recovered from anesthesia. Affected muscles may be swollen, hot, and painful on deep palpation; and the horse is often reluctant to bear weight on the affected limb. Myasthenia (weakness) of affected muscles is common, particularly with peripheral nerve involvement. In some horses this condition may limit the animal's ability to stand for some time after anesthesia. The loss of muscle strength, particularly when involving adductor muscles, can contribute to orthopedic injury during repeated attempts to rise. Many horses with mild to moderate muscle injury recover over a period of [148]

hours to days even if untreated.[148]

Fig. 42-15 Postanesthetic myoneuropathy showing paralysis of the right femoral and peroneal nerves.

42.7.4.3.3.2

Etiology

A variety of factors acting alone or in combination have been suggested to contribute to this disorder. The most important factors include ischemia and hypoperfusion as a result of prolonged immobility, muscle compression, systemic hypotension, and hypoxia.[148–152] There is increased lactate efflux from dependent muscles during anesthesia in horses that develop a myopathy, supporting the contention that these muscles experience compromised perfusion.[151,152] Halothane anesthesia has a greater propensity than isoflurane to compromise tissue oxygen delivery even in nondependent muscles.[150] If mean arterial pressure is allowed to fall below 55 to 65 mm Hg for several hours during inhalation anesthesia, particularly if mechanical ventilation is not used, the incidence of postanesthetic myopathy increases substantially.[152]

42.7.4.3.3.3

Diagnosis

Diagnosis is based on a history of anesthesia or prolonged recumbency, clinical signs, and possibly clinical pathology examinations. Laboratory findings include elevations in serum CK and subsequently serum AST and serum LDH activities. Elevations in CK levels of thousands to tens of thousands of international units per liter are commonly demonstrated in horses with moderate forms of the myopathy.

42.7.4.3.3.4

Treatment

Horses demonstrating only minor localized manifestations of the myopathy usually have an uncomplicated recovery with little or no treatment.[148] Supportive care, including the use of antiinflammatory drugs, DMSO, and dantrolene sodium 2 to 4 mg/kg PO, often is sufficient in mild to moderate cases.[153] Significant muscle atrophy may develop over the ensuing 3 to 4 weeks but usually will resolve within 2 to 3 months. Treatment of more severe cases is outlined under generalized reactions.

42.7.4.3.3.5

Control

Correct positioning and judicious use of padding and water- or air-filled mattresses can reduce dependent muscle pressure up to 50%, thereby aiding in the reduction of this disorder. In addition, through elevation of the upper limb during anesthesia, the pressure on the lower limbs is significantly reduced. Pulling the lower forelimb forward also markedly reduces pressure in the dependent triceps muscle. When the horse is in dorsal recumbency, padding under the shoulders and hips is absolutely imperative.

Maintaining anesthesia at the lightest plane possible for a specific surgical procedure is beneficial in prophylaxis. Similarly, if possible, maintaining systemic mean arterial blood pressure above 80 to 85 mm Hg during anesthesia is advisable. The use of inotropic agents such as dobutamine during anesthesia has been useful in reducing the occurrence of anesthetic myopathies. Administration of dantrolene sodium (2 to 4 mg/kg PO) 1 hour before induction of anesthesia may result in a reduction in the incidence of this myopathy in some susceptible horses.

42.7.4.3.4

Generalized Anesthetic Reactions

42.7.4.3.4.1

Clinical Signs

Postanesthetic reactions involving multiple muscle groups can result in clinical signs of anxiety, tachycardia, tachypnea, profuse sweating, and myoglobinuria.[149,150] Horses may not be able to rise and may struggle violently, resulting in prolonged, traumatic recoveries. In some cases a progressive increase in body temperature and muscular contractures may develop under anesthesia, and a fulminant metabolic and respiratory acidosis may be noted.[27,154,155] These animals can die within a matter of hours. In some cases, shock and pigmenturia may lead to renal failure.

42.7.4.3.4.2

Pathogenesis

The generalized form of myopathy cannot be explained by the compartmental syndrome alone. Halothane and succinylcholine have been the most frequently implicated inciting agents for generalized anesthetic-induced myonecrosis in all susceptible species, including the horse.[26,154,155] There appear to be several possible explanations for generalized anesthetic reactions. In some cases, systemic hypotension and hypoxemia may create local ischemic lesions, with the pathologic changes becoming more generalized as a result of the stress of anesthesia and the sensitivity of muscle cells to anesthetic agents or muscle relaxants.[148,152] In other cases, MH[26,154–156] may be responsible for clinical signs of

muscle contracture, heat production, and systemic acidosis resulting from excessive calcium release by the sarcoplasmic reticulum. In swine, MH is caused by a genetic mutation in the ryanodine receptor 1 gene,[157,158] and recently a mutation in the same gene was identified in two quarter horses that developed fatal MH after direct mask induction with halothane.[159,160] A further possible cause of generalized anesthetic myopathies is the triggering of severe myonecrosis in horses with an underlying exertional myopathy. Horses with recurrent ER may be at risk for excessive release of calcium from the sarcoplasmic reticulum during halothane anesthesia, and horses with polysaccharide storage myopathy (PSSM) may develop rhabdomyolysis because of metabolic changes with anesthesia.[26,27,161,162]

42.7.4.3.4.3

Diagnosis

Diagnosis is based on clinical signs, particularly in horses undergoing inhalation anesthesia. Routine monitoring of body temperature during anesthesia may aid in the early detection of MH. Some animals may also demonstrate metabolic and respiratory acidosis and hyperkalemia.[159] Genetic screening for MH or PSSM may be warranted before elective procedures. In humans, individuals suspected of being susceptible to MH may be identified using a halothane-caffeine contracture test. Several horses showing signs of MH have had a positive response to this test.[26,27] However, the test is rather complex to perform and is neither readily available nor feasible for detection of MH-susceptible horses.

1410
1411

42.7.4.3.4.4

Treatment

Severely affected animals provide a significant therapeutic challenge. Aims of therapy should include (1) relief of pain, (2) correction of fluid and electrolyte abnormalities, (3) attempts to prevent ongoing necrosis, and (4) high-quality nursing care.

Many of the same principles described for treatment of ER can be used for treatment of postanesthetic myoneuropathy (see p. 1413). In severely affected recumbent horses, pain relief and sedation may help prevent struggling and progression of the myopathy.[148,149] Detomidine combined with butorphanol is effective in reducing struggling. Violent struggling only exhausts the horse and increases the potential for further injury and muscle damage. Constant rate infusions of butorphanol, opioids, or detomidine may aid in pain control where practical. Similarly, administration of NSAIDs may help reduce ongoing degenerative changes in muscle. Dantrolene sodium 2 to 4 mg/kg PO every 6 to 8 hours decreases release of calcium from the sarcoplasmic reticulum, helping to break the cycle of muscle damage. Volume expansion and diuresis may prevent renal toxicity.[148]

The most common metabolic derangement with anesthetic-related myopathies is a metabolic and/or respiratory acidosis. If specific therapy for metabolic acidosis is necessary, intravenous administration of sodium bicarbonate can be used. For optimum results, doses are calculated on the basis of the results of acid-base analysis. If facilities for acid-base analysis are not available and the horse appears severely compromised, intravenous administration of sodium bicarbonate at a dose of 1 to 2 mEq/kg slowly is recommended. If hyperthermia and contracture develop during anesthesia, discontinuation of anesthesia is advisable. Additional attempts to cool the animal with alcohol or cold-water baths may also be indicated. Administration of a large amount of soluble, lyophilized dantrolene sodium for intravenous administration may alleviate clinical signs in these horses. However, availability and expense of the agent in this form restrict its use. A dosage rate of 1 mg/kg IV may be appropriate, although more controlled studies are required.[148]

Good nursing care is important in severely affected horses. This involves providing well-padded areas on which horses can lie. Prevention or minimization of trauma around the eyes and appropriate care of decubital sores are important. Recumbent animals may require frequent turning to allow reperfusion of compressed muscle masses. Continued fluid therapy with polyionic fluids and possibly caloric supplementation may be indicated. The use of slings and pools to assist recumbent animals to rise also has been tried.[148] Recovery from the myopathy may occur with no apparent residual lesions. In contrast, recovery from some severe forms of the disorder may be accompanied by muscle atrophy, fibrosis, and scarring.[148]

42.7.4.3.4.5 Prevention

The principles described for localized myoneuropathies apply to the prevention of generalized anesthetic-related myopathies. In addition, dantrolene sodium has been shown to reduce the incidence of MH in susceptible humans and pigs. Similar effects might be anticipated in horses. Because of limited controlled studies, the dosage rate for prevention of MH in the horse is not clearly defined. Administration at a rate of 4 mg/kg PO 1 to 2 hours before anesthesia may be beneficial in reducing the incidence of MH.[153,163]

42.7.5 EXERTIONAL MYOPATHIES IN HORSES

42.7.5.1 LOCAL MUSCLE STRAIN

STEPHANIE J. VALBERG

42.7.5.1.1 Lumbar and Gluteal Muscles

Strain of lumbar and gluteal muscles is common in jumpers, dressage, and harness horses. Several factors may predispose horses to muscle strains, such as an inadequate warmup, preexisting lameness, exercise to the point of fatigue, and insufficient training. Lameness is often mild, and horses usually are reluctant to engage their hindquarters during exercise. Deep palpation of epaxial and gluteal muscles results in pain and dorsiflexion of the spine. Horses that show pain but resist dorsiflexion, ventriflexion, and lateral bending on manipulation may have a myopathy secondary to an underlying disorder of the spine or sacroiliac joint.

42.7.5.1.2 Adductor Muscles

The gracilis muscle can be torn in horses and cause severe pain and occasionally recumbency.[164,165] A careful physical examination reveals swelling of the medial thigh and pain on palpation. Ultrasonography identifies the extent of disrupted muscle fibers.

42.7.5.1.2.1 Treatment

Adequate rest and NSAIDs form the basis for treatment. Hand walking once the initial stiffness has dissipated may be beneficial. In addition, massage and the intermittent application of heat may aid the healing process. Exercise should be resumed gradually, preceded by an appropriate warmup period in a long and low frame. Adequate conditioning should be ensured before strenuous exercise is started. Saddles should be checked for proper fit.

42.7.5.1.3

Semitendinosus and Semimembranosus Muscles

ANDREW J. DART

Semitendinosus and semimembranosus muscles are frequently damaged in working quarter horses and in chronic cases result in a fibrotic myopathy.[166–169] Tearing of the semitendinosus and sometimes the semimembranosus, biceps femoris, and gracilis muscles at the point of a tendinous insertion is usually associated with work that requires abrupt turns and sliding stops. Horses caught in ropes or fences may struggle violently enough to induce sufficient trauma, allowing subsequent development of the myopathy. In one report, 5 of 18 horses developed this condition secondary to intramuscular injections.[168] A congenital form of fibrotic myopathy has been described.[170] Affected animals are usually less than 12 months old when clinical signs characteristic of fibrotic myopathy are first evident. Horses affected with this form of the disorder frequently have no palpable thickening of affected muscles or tendons and no history or evidence of trauma.

Affected muscles in acute cases are painful on deep palpation and may appear warm. Chronically, hardened areas within the muscle may represent fibrosis and ossification. The lameness in chronic cases is usually most apparent at the walk and is characterized by an abrupt cessation of the anterior phase of the stride of the affected limb, causing the leg to jerk suddenly to the ground rather than continue its forward motion. Pain is not a feature in chronic fibrotic myopathy, and manipulative tests have little, if any, effect on the degree of dysfunction. The stride has a short anterior phase with a characteristic hoof-slapping gait. The gait reflects a mechanical hindlimb lameness that restricts normal function. Radiographs may indicate ossification of affected muscles.[168,170]

1411 1412

42.7.5.1.4

Diagnosis

Serum activities of CK and AST are usually only mildly elevated. In addition to palpation, diagnosis can be confirmed by ultrasonography, thermography, or scintigraphy. Light microscopic evaluation of muscle biopsies is frequently normal in acute cases. Chronically fibrous replacement of muscle fibers is apparent.

42.7.5.1.5

Treatment

Several surgical procedures for correction of fibrotic myopathy have been described. These involve either excision[168] or transection[167] of the fibrotic part of the muscle or tenotomy of the tibial insertion of the semimembranosus tendon.[170] Excision of the fibrotic part of the muscle and tenotomy of the tibial insertion of the semimembranosus tendon are performed with the animal under general anesthesia. Excision or transection appears to produce more postoperative complications than tenotomy. However, according to reports, tenotomy has been reported in only a limited number of horses, and complete resolution of the gait abnormality may not occur.[169] In a modification of the procedure described by Irwin and Howell,[167] transection of the fibrotic mass in the standing horse under local anesthesia using a

bistoury knife may be effective. A Penrose drain is inserted through a second incision ventral to the first, and light exercise is resumed the day after surgery. Healing is allowed to occur by second intention.

42.7.6 EXERTIONAL RHABDOMYOLYSIS

STEPHANIE J. VALBERG

ER is probably the most common muscle disorder in horses. It is a frequent cause of poor performance in a variety of breeds, including standardbreds, thoroughbreds, warmbloods, Arabians, Morgans, quarter horses, Appaloosas, and American Paint horses. ER is a complex syndrome that likely has numerous causes. Numerous terms such as *tying up, chronic intermittent rhabdomyolysis, azoturia, Monday morning disease, paralytic myoglobinuria,* and *exercise-associated myositis* have been used for this syndrome.

42.7.6.1 Clinical Signs

Classically, horses develop a stiff, stilted gait, with excessive sweating and a high respiratory rate during or after exercise (Fig. 42-16). Most commonly, signs are seen after only 15 to 30 minutes of light exercise. After exercise, horses may stretch out as if to urinate, become extremely reluctant to move their hindquarters, and in severe cases show signs of colic or become recumbent.[15,171] Attempts to move more severely affected animals may result in extreme pain, obvious anxiety, and possible exacerbation of the condition. Firm painful muscles may be palpated over the back and hindlimbs. Scintigraphic evaluation of horses with rhabdomyolysis after exercise shows symmetric damage to the gluteal, semitendinosus, and semimembranosus muscles.[22] Myoglobinuria is a classic feature of more severely affected horses.[171,172] Endurance horses often show other signs of exhaustion including a rapid heart rate, dehydration, hyperthermia, SDF, and collapse.[73]

Fig. 42-16 Exertional rhabdomyolysis in a horse showing signs of pain, stiffness, sweating, and elevated respiratory rate.

42.7.6.2 Etiology

Several factors appear to precipitate episodes of ER. Some successful athletic horses may experience one or two isolated episodes of rhabdomyolysis during their lifetime, suggesting that environmental influences play an important role in sporadic cases.[173–177] Other horses may have chronic episodes of rhabdomyolysis that compromise their ability to compete. An inherent muscle dysfunction precipitated by certain triggering factors likely contributes to rhabdomyolysis in these horses.[14,178,179] ER is a syndrome that has many causes. To identify the cause in individual horses it may be helpful to initially subdivide cases into those with no intrinsic muscle abnormality (extrinsic or sporadic form) and those with a suspected intrinsic abnormality of muscle function (intrinsic or chronic form). Causes for sporadic and chronic exercise-induced muscle damage are listed in Box 42-1.

42.7.6.3

Sporadic Exertional Rhabdomyolysis

Most cases of ER can be diagnosed on the basis of the animal's history and clinical signs. Confirmation of rhabdomyolysis requires determination of abnormally elevated serum CK, serum AST, or serum LDH. Serum CK is often in the tens to hundreds of thousands of international units per liter, and AST in the thousands to tens of thousands.[9,171] The degree of elevation in enzymes reflects the time lapse between rhabdomyolysis and obtaining a blood sample, as well as the extent of myonecrosis. Myoglobinuria is a common finding in severely affected horses.

42.7.6.3.1

OVEREXERTION

The most common cause of sporadic ER is exercise that exceeds the horse's underlying state of training.[180] This includes both high-intensity exercise and endurance riding. Tears in the junctions between intracellular myofilaments (Z lines) are a common cause of postexercise muscle soreness.[9,181] ER that occurs at the end of endurance rides is covered in the section of this chapter that discusses exhaustion in endurance horses.

42.7.6.3.2

CONCURRENT ILLNESS

The incidence of muscle stiffness and ER has been observed to increase during an outbreak of respiratory disease.[103] Both equine herpesvirus 1 and equine influenza virus have been implicated as causative agents.[104] Mild muscle stiffness with concurrent viral infections is likely the result of the release of endogenous pyrogens.

42.7.6.3.3

ELECTROLYTE IMBALANCES

Electrolyte depletion in horses can occur as a result of dietary deficiency and losses in sweat with strenuous exercise.[11,182] Sodium, potassium, magnesium, and calcium play key roles in muscle fiber contractility. With severe electrolyte depletion after exercise, serum electrolytes may be below normal ranges.[183] These problems are common in endurance horses and are covered in the section on exhaustion in endurance horses. With chronic dietary depletion, however, serum concentrations may not reflect total body electrolyte imbalances. Work by Harris[11] established renal FE as a technique to evaluate electrolyte concentrations in horses with chronic ER. Normal values are dependant on diet and can vary from day to day and horse to horse.[12] In the United Kingdom, horses with chronic ER were shown to have low FEs of

sodium, and daily dietary supplementation of 2 oz of NaCl resulted in abatement of clinical signs.[11] Other horses had high phosphorus excretion, suggesting dietary calcium:phosphorus imbalance, and decreasing bran while providing a daily calcium supplement (2 oz of $CaCO_3$) was helpful in reducing clinical signs of ER. Hypokalemia has also been suggested to play a role in chronic ER. Hypokalemia was determined through low RBC potassium concentrations, which may not reflect total body potassium or low muscle potassium concentrations.[184,185] Supplementation with good-quality forage or 1 oz of KCl per day (Lite salt) is recommended for horses with low renal FE of potassium. Most horses fed on pasture or with high-quality hay do not appear to be potassium depleted.

42.7.6.3.4

VITAMIN E AND SELENIUM DEFICIENCY

The increased oxidative metabolism associated with exercise results in the generation of free radicals. Selenium, acting via the enzyme glutathione peroxidase, and vitamin E, acting within the lipid component of cell membranes, scavenge free radicals and prevent lipid peroxidation of cell membranes. Primary selenium deficiency is common in young animals living in areas with selenium-deficient soil; however, it has rarely been demonstrated as a cause of ER. Many horses with chronic ER have higher concentrations of selenium because of zealous dietary supplementation by owners.[186] Vitamin E deficiency occurs in horses that have limited access to pasture and consume poor-quality hay. It is not known whether horses that experience repeated episodes of ER may generate more free radicals than normal horses. A higher generation of free radicals in horses with chronic ER may explain the perceived benefit of repeated administration of selenium and vitamin E in thoroughbred horses with recurrent ER. Adequate values for blood selenium are greater than 0.07 mcg/mL and for serum vitamin E greater than 1.1 mcg/mL.

42.7.6.3.5

SOLUBLE CARBOHYDRATES

Horses consuming a high-grain diet appear to be more likely to develop ER than horses fed a low-grain fat-supplemented diet. The reason for this is unclear and may differ among forms of chronic ER. For example, in horses with PSSM, high—soluble-carbohydrate diets may enhance glucose uptake and glycogen storage.[187] In horses with recurrent ER, however, glycogen storage does not increase substantially even though serum CK activities are highest on high-grain diets.[188–190] Dietary effects in recurrent ER may in part be related to the psychogenic effects of grain on excitability.

42.7.6.3.6

HORMONAL IMBALANCES

A contribution of reproductive hormones to triggering ER has been postulated because the incidence of some forms of chronic ER appears to be highest in mares. Many owners report that episodes of rhabdomyolysis occur most commonly during estrus, but in one study of racehorses no direct correlation was shown between progesterone fluctuations and serum CK activity.[191] It is likely that the estrous cycle is one of many factors that combine to trigger ER in susceptible horses. In some mares in which episodes of ER coincide with estrus, suppression of estrus using progesterone implants or injections may be helpful. This should be done in conjunction with dietary and training alterations. Hypothyroidism has also been suggested as a cause of ER, but this has never truly been substantiated.

42.7.6.3.7

LACTIC ACIDOSIS

Although lactic acidosis has been postulated as a cause of ER, a significant lactic acidosis never has been documented.[188,192,193] Horses are most prone to development of ER during submaximal exercise. Blood lactate and muscle lactate concentrations in standardbreds, thoroughbreds, and quarter horses that develop rhabdomyolysis are substantially lower than those seen in healthy horses after racing. The most common metabolic derangement in horses with severe rhabdomyolysis is a hypochloremic metabolic alkalosis.[118,194] Therefore there seems to be little scientific evidence to support this theory.

42.7.6.4

Treatment

Treatment of ER is directed at relieving anxiety and muscle pain and replacing fluid and electrolyte losses. Tranquilizers such as acepromazine (0.04 to 0.07 mg/kg), xylazine (0.4 to 1 mg/kg), or detomidine (0.02 to 0.04 mcg/kg) combined with butorphanol (0.01 to 0.04 mg/kg) provide excellent sedation and analgesia. For horses with extreme pain and distress, a constant rate infusion of detomidine, lidocaine, or butorphanol may provide additional pain relief. NSAIDs such as ketoprofen (2.2 mg/kg), phenylbutazone (2.2 to 4.4 mg/kg) or flunixin meglumine (1.1 mg/kg) are frequently used to relieve pain but should be used with caution in dehydrated animals. Intravenous or intragastric DMSO (as a <20% solution) is used as an antioxidant, antiinflammatory, and osmotic diuretic for severely affected horses. Methylprednisolone succinate (2 to 4 mg/kg IV) has been advocated in the acute stage by some veterinarians if horses are recumbent. Muscle relaxants such as methocarbamol (5 to 22 mg/kg IV, slowly) seem to produce variable results, possibly depending on the dose used. The administration of Dantrium (dantrolene sodium) (2 to 4 mg/kg PO) in severely affected horses may decrease muscle contractures and possibly prevent further muscle necrosis. The dose can be repeated every 4 to 6 hours if necessary. Overdosing produces muscle weakness.

Severe rhabdomyolysis can lead to renal compromise owing to the ischemic and the combined nephrotoxic effects of myoglobinuria, dehydration, and NSAIDs. In mildly dehydrated horses, provision of free-choice electrolytes and water or administration of fluids via a nasogastric tube may be adequate. Horses with moderate to severe dehydration require intravenous administration of balanced polyionic electrolyte solutions. Hyperkalemia can occur with severe rhabdomyolysis, necessitating the use of isotonic sodium chloride. If hypocalcaemia is present, then supplementing intravenous fluids with 100 to 200 mL of 24% calcium borogluconate is recommended, but serum calcium should not exceed a low-normal range. Affected animals are usually alkalotic, making bicarbonate therapy inappropriate. In severely affected animals, regular monitoring of serum creatinine is advised to assess the extent of renal damage.

Horses with rhabdomyolysis should be stall rested on a hay diet for a few days. Small paddock turnout in a quiet area for a few hours twice a day is then helpful. Horses may be hand walked at this time, but more than 5 to 10 minutes at a time may induce another episode of rhabdomyolysis. For horses with sporadic forms of tying-up, rest with regular access to a paddock should continue until serum muscle enzyme concentrations are normal. For chronic cases of tying-up, this much rest may not be appropriate. Training should be resumed gradually, and a regular exercise schedule that matches the degree of exertion to the horse's underlying state of training should be established. Endurance horses should be supplemented with electrolytes and water during an endurance ride and monitored particularly closely during hot, humid conditions.

1413

1414

42.7.6.5

Prevention

Because the inciting cause is usually temporary in sporadic cases, most horses respond to a few weeks of rest, dietary adjustments, and a gradual increase in training. The diet should be adjusted to include high-quality grass hay (or less than 50% alfalfa hay) and the minimum amount of soluble carbohydrate necessary (grains, sweet feed, molasses). A ration balancer containing protein, vitamins, and minerals should be added if necessary. If more than 3 to 5 kg of grain per day is necessary to maintain body weight, the addition of a fat source such as vegetable oil, rice bran, or a complete high-fat, low-starch feed should be considered. The horse should receive on a daily basis an electrolyte supplement that contains at least 1 oz of sodium chloride. A vitamin E and selenium supplement may be necessary in areas with low soil selenium. In addition, myriad treatments are commercially available that are guaranteed to cure tying-up in horses. Many of these have yet to be scientifically tested for efficacy. Skeletal muscle shows remarkable ability to regenerate after injury. After ER complete repair of muscle tissue is possible within 4 to 8 weeks.

42.7.6.6 Chronic Exertional Rhabdomyolysis

Many horses have repeated episodes of rhabdomyolysis with minimal exercise, even when the dietary and training recommendations for sporadic ER are followed. Forms of chronic ER are seen in many breeds of horses including quarter horses, American Paint horses, Appaloosas, thoroughbreds, Arabians, standardbreds, Morgans, draft breeds, and warmbloods. Current research suggests that many of these horses are susceptible to rhabdomyolysis because of an inherent disorder in muscle function.[179,195] Rhabdomyolysis in such horses occurs as a result of specific environmental circumstances that trigger muscle necrosis in genetically susceptible animals. Two heritable causes of chronic ER have recently been identified, but there may be several others that are yet unidentified. These include a glycogen storage disorder called *polysaccharide storage myopathy* and a disorder of muscle contractility called *recurrent exertional rhabdomyolysis*.[14,26,196] Distinguishing among the various forms of chronic ER requires a thorough history, dietary evaluation, physical examination, determination of serum and urine electrolyte concentrations, assessment of serum vitamin E and whole blood selenium concentrations, and histologic evaluation of muscle biopsies using special stains.

42.7.6.7 Polysaccharide Storage Myopathy

A subset of horses with chronic ER includes horses found to have a glycogen storage disorder characterized by the accumulation of glycogen and an abnormal polysaccharide in their muscle.[196] To date, quarter horses, Paint horses, Appaloosas, Morgans, draft horses, draft cross-breds, warmbloods, and a few thoroughbred and Arabian horses have been identified as having PSSM.[197–201]

42.7.6.8 Diagnosis

A definitive diagnosis of PSSM can be made only by evaluation of a muscle biopsy sample.[196] Supportive evidence of PSSM in quarter horses includes clinical signs of ER, persistent elevations in serum CK and AST activities, and a minimum threefold elevation in CK activity 4 hours after an exercise test consisting of a maximum of 15 minutes of lunging at a walk and trot.[193] Supportive evidence in draft and warmblood breeds includes exercise intolerance, muscle atrophy, weakness, and some gait abnormalities without necessarily finding elevations in muscle enzymes.[161,201,202]

A muscle biopsy of any locomotor muscle that provides a 2-cm × 1-cm block of tissue for evaluation is often

A muscle biopsy of any locomotor muscle that provides a 2-cm × 1-cm block of tissue for evaluation is often sufficient for analysis. The site most easily sampled in the field using an open surgical approach is the semimembranosus or semitendinosus muscle. Clinics that can rapidly process muscle for frozen sections often use a modified Bergstrom biopsy instrument inserted into the gluteal muscle through a 1-cm incision. A diagnosis can be made irrespective of diet and proximity of sampling to recent episodes of rhabdomyolysis. The characteristic features in histologic sections include the presence of subsarcolemmal vacuoles, increased staining for amylase-sensitive glycogen in periodic acid—Schiff (PAS) stain, and the presence of amylase-resistant PAS-positive abnormal polysaccharide inclusions in skeletal muscle fibers (Fig. 42-17).[25,196] Laboratories that use the acronym EPSM process formalin-fixed muscle tissue; the diagnostic criteria used in such laboratories may be those described previously, but in addition these laboratories allow the sole criteria for diagnosis to be increased staining for amylase-sensitive glycogen or the presence of PAS-positive sarcoplasmic masses.[198] A much wider spectrum of breeds is diagnosed with PSSM using these criteria, and the specificity for diagnosis is decreased.

42.7.6.8.1

POLYSACCHARIDE STORAGE MYOPATHY IN QUARTER HORSE—RELATED BREEDS

A survey of 164 quarter horses used mainly for breeding or ranch work found that 6% of these horses had PSSM based on identifying amylase-resistant abnormal polysaccharide in skeletal muscle biopsies.[203] These horses were kept on pasture, fed very little grain, and showed no clinical signs of a myopathy. In contrast, 50% of muscle biopsy samples from quarter horse—related breeds submitted to the Neuromuscular Diagnostic Laboratory at the University of Minnesota because of signs of a neuromuscular disorder are diagnosed with PSSM.[197] PSSM appears to be a common cause of neuromuscular disease in quarter horse—related breeds, however, under certain environmental conditions clinical signs may be inapparent.

42.7.6.8.1.1

Genetics

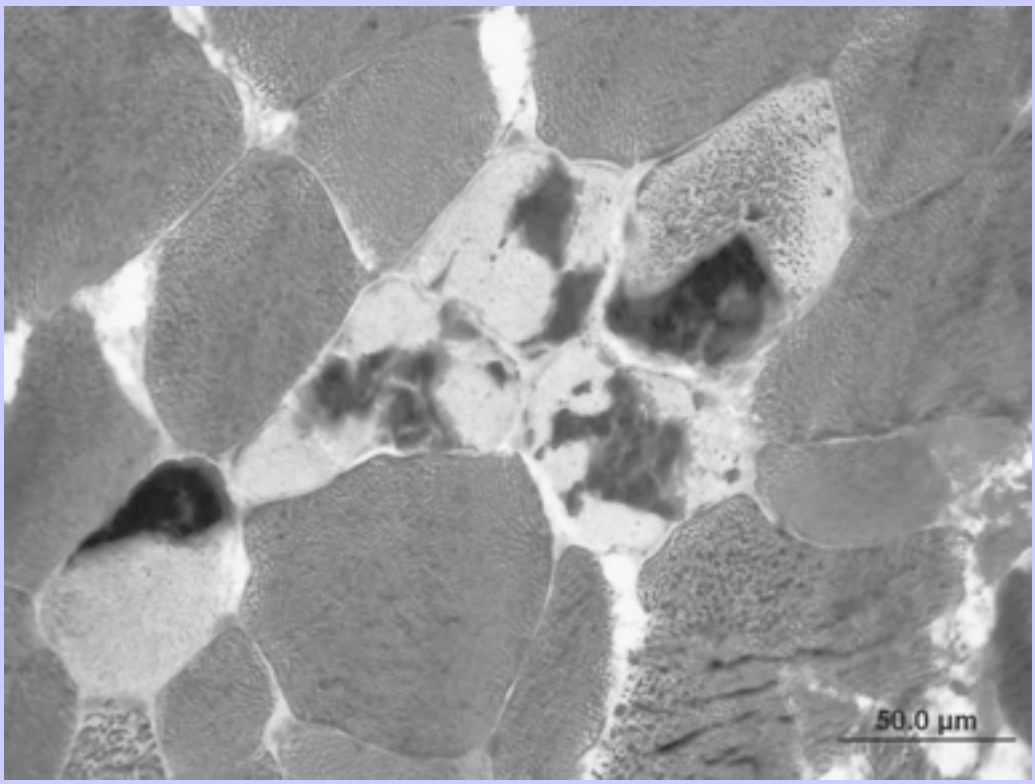
Although in general the prevalence of PSSM is 6% of quarter horses, on some breeding farms the prevalence can be as high as 42%.[203] This suggests that PSSM may be inherited within particular bloodlines. A familial basis for PSSM has been suggested from pedigree analysis and by limited breeding trials at the University of Minnesota.[195,204] Although pedigree analysis initially supported an autosomal recessive pattern of inheritance, identification of PSSM in quarter horse crosses indicates that a dominant mode of inheritance is more likely.

1414

1415

Fig. 42-17 Periodic acid—Schiff stain for glycogen in a gluteal biopsy from a horse with polysaccharide storage myopathy showing

aggregates of intensely staining abnormal polysaccharide in some fibers.



42.7.6.8.1.2

Clinical Signs

The average age of onset of clinical signs of PSSM is 5 years in quarter horses, and ranges from 1 to 14 years of age.[178] There is no significant temperament, body type, or gender predilection for PSSM. Approximately 40% of owners believe there is a seasonal incidence to the development of clinical signs. The most common trigger for clinical signs of PSSM is less than 20 minutes of exercise at a walk and trot, particularly if the horse has been rested for several days before exercise. Signs of ER include firm painful muscles, stiffness, fasciculations, sweating, weakness, and reluctance to move. The hindquarters are frequently most affected, but back muscles, abdomen, and forelimb muscles may also be involved. During exercise, horses may stop and posture as if to urinate, perhaps as a means to alleviate muscle cramping (Fig. 42-18). Signs of pain can be particularly severe, with 30% of horses exhibiting muscle pain for more than 2 hours and approximately 10% of cases becoming recumbent. Less common signs of PSSM in quarter horses include gait abnormalities, mild colic, and muscle wasting.

Quarter horses frequently exhibit elevations of serum CK and AST in association with clinical signs. The median CK and AST levels for all PSSM quarter horses with muscle biopsy samples submitted to the Neuromuscular Diagnostic Laboratory at the University of Minnesota were 2809 and 1792 U/L, respectively. Persistent elevation in CK activity, despite an extended period of rest, is a common observation in PSSM quarter horses.[15]

42.7.6.8.2

POLYSACCHARIDE STORAGE MYOPATHY IN DRAFT BREEDS

The prevalence of PSSM among draft breeds with biopsy samples submitted to the NDL at the University of Minnesota is 54%.[197] The breeds most commonly diagnosed with PSSM at the NDL in Minnesota are Belgians, Percherons, and crosses of these breeds with light horses. A prospective by Firshman and co-workers found a prevalence of PSSM of 36% in Belgian draft horses.[202]

42.7.6.8.2.1

Genetics

Several full- and half-sibling Belgian horses have been identified with PSSM, and many Belgian—light breed crosses have been identified with PSSM, indicating a potential genetic basis.

42.7.6.8.2.2

Clinical Signs

The average age of draft horses diagnosed with PSSM is approximately 8 years.[197,202] No particular gender predilection has been identified for PSSM in draft horses. It is notable that clinical signs are not consistently present with PSSM, as many of the Belgian draft horses that were positive for PSSM in the study by Firshman and colleagues had no clinical signs.[202] PSSM in draft horses likely is the same disorder described as “Monday morning disease” in work horses in the early twentieth century.[172] ER is a manifestation of PSSM in draft horses as well as draft crosses and can be so severe that it leads to recumbency and death.[201,205] In addition, postanesthetic myopathy may also be a complication of PSSM in draft breeds.[161] A number of draft horses with PSSM show signs of progressive weakness and muscle loss resulting in difficulty rising. In these cases serum CK activity is frequently normal. Gait abnormalities, such as excessive limb flexion, fasciculations, and trembling are commonly seen with PSSM in draft horses. Although the condition “shivers” was previously attributed to PSSM,[206] a recent study found no causal association between these two conditions.[202] The very high prevalence of PSSM in draft horses in essence means that there is a 36% chance that any clinical sign could be falsely associated with the disease PSSM. Therefore clinical judgment is required to determine whether the muscle biopsy results could reasonably be associated with a myopathic process or if other possible causes of muscle weakness or gait changes should also be investigated.

Fig. 42-18 Typical stance of a horse with PSSM after 10 minutes of walking and trotting. Note the tucked-up abdomen and

camped-out stance, which were concurrent with firm muscles, fasciculations in the flank, and elevated serum creatine kinase activity.

Serum muscle enzyme activities are often normal in draft horses with PSSM. The median serum CK and AST levels in draft horses from which biopsies were sent to the NDL at the University of Minnesota were 459 and 537 U/L.[197] Mean CK and AST activities in the Belgian horse study by Firshman were 326 ± 380 U/L and 355 ± 193 U/L, respectively. Serum vitamin E and whole blood selenium concentrations are normal in draft horses with PSSM.[202]

42.7.6.8.3

POLYSACCHARIDE STORAGE MYOPATHY IN WARMBLOODS

The true prevalence of PSSM in other horse breeds remains to be established. Based on the number of horses diagnosed with PSSM from muscle biopsy samples submitted to the NDL, PSSM appears to be a common neuromuscular disorder in warmblood horses, with approximately 50% of warmblood biopsy samples being diagnosed with PSSM.[197] This included a wide variety of warmblood breeds, such as Dutch warmblood, Hanoverian, Westfalian, Canadian warmblood, Irish sport horse, Gerdlander, Hussien, and Rheinlander. No reports on the potential inheritance of PSSM in warmbloods have been published.

42.7.6.8.3.1

Clinical Signs

The mean age of onset of clinical signs in warmbloods is reported to be 8 to 11 years of age.[197,207] A gender predilection for PSSM has not been identified. The most common clinical signs reported in warmbloods with PSSM are painful firm back and hindquarter muscles, reluctance to collect and engage the hindquarters, poor rounding over fences, gait abnormalities, and atrophy. Overt signs of ER, such as stiffness, shortness of stride, and reluctance to move after exercise were reported in less than 15% of warmbloods with PSSM.[197] The median CK and AST levels in warmbloods diagnosed with PSSM at the NDL in Minnesota are 323 and 331 U/L, respectively.

42.7.6.8.4

POLYSACCHARIDE STORAGE MYOPATHY IN OTHER BREEDS

A few horses of other breeds have been reported to have PSSM. The prevalence of PSSM within these breeds appears to be quite low. For example, although more than 50% of biopsies of quarter horses, draft horses, and warmbloods resulted in diagnosis of PSSM, fewer than 10% of muscle biopsies from 178 thoroughbreds, 40 Arabians, and 32 standardbreds with neuromuscular disease resulted in diagnosis of PSSM. A slightly higher prevalence was found for Morgans and Tennessee Walking Horses.[197] Previous published reports of PSSM based on amylase-resistant polysaccharide include small numbers of horses of warmblood cross-breeds, Anglo-Arabs, Andalusians, Morgans, Arabians, Welsh cross-breeds, and standardbred breeds.[198] Some of the controversy regarding the number of breeds affected with PSSM may be a result of inclusion of cases with sarcoplasmic masses and increased PAS staining for glycogen as positive criteria for PSSM by some laboratories.

1415

1416

42.7.6.9

Pathophysiology

Muscle glycogen concentrations in PSSM horses are often one and a half to four times normal, and glucose-6-P concentrations are up to 10 times normal.[115] Glycogen accumulation in PSSM horses is not the result of an inability to metabolize glycogen but rather of increased synthesis of glycogen. There appear to be at least two linked biochemical abnormalities associated with PSSM. The first abnormality is expressed as enhanced sensitivity to insulin in quarter horses with PSSM horses as determined by intravenous or oral glucose tolerance tests as well as euglycemic hyperinsulinemic clamping.[208,209] In association with high dietary starch intake, this enhanced insulin sensitivity may increase uptake of glucose into skeletal muscle and the subsequent formation of glycogen. Draft horses have not been found to have heightened insulin sensitivity. The second biochemical abnormality in horses with PSSM is associated with abnormal regulation of glycogen synthase, resulting in persistent glycogen synthesis. Abnormal polysaccharide formed in PSSM skeletal muscle is less highly branched than normal glycogen and may reflect an imbalance in the heightened activity of glycogen synthase relative to the less tightly regulated glycogen branching enzyme. Abnormal polysaccharide is also occasionally found in the heart of PSSM horses but has not been identified in the liver.

The development of rhabdomyolysis in PSSM horses is not directly associated with heightened insulin sensitivity.[210] If PSSM horses are treated with dexamethasone, their insulin sensitivity can be reduced to well within the normal range; however, they still develop rhabdomyolysis. Rather, muscle necrosis with exercise appears to be associated with a separate but potentially linked biochemical abnormality in energy metabolism. During submaximal exercise, muscle fibers in PSSM horses do not generate adequate energy for muscle contraction, as evidenced by the degradation of adenine nucleotides in individual muscle fibers.[211] It is likely that PSSM is caused by a defect in a pathway that controls both the flux of substrates such as glucose into the cell, as well as the flux of substrates such as glycogen and free fatty acids through metabolic pathways during aerobic exercise.

42.7.6.10 ## Treatment and Prevention

Horses diagnosed with PSSM will always have an underlying predilection for muscle soreness. The best that can be done is to manage horses to minimize clinical signs. With adherence to diet and exercise recommendations, at least 80% of horses show notable improvement in clinical signs, and many return to acceptable levels of performance.[178,212] There is, however, a wide range in the severity of clinical signs shown by horses with PSSM; horses with severe or recurrent clinical signs will require more stringent adherence to diet and exercise recommendations in order to regain muscle function.

Treatment of horses with acute rhabdomyolysis is similar to that described for sporadic ER except that PSSM horses should not be confined to a stall for more than 48 hours. They should be provided turnout in paddocks of gradually increasing size once stiffness has subsided. Hand walking horses recovering from an episode of PSSM for more than 5 to 10 minutes at time may trigger another episode of rhabdomyolysis.

42.7.6.10.1 ### EXERCISE REGIMES

Horses with PSSM should be given 2 weeks to adapt to a new diet before commencing exercise. Less than 10 minutes of a relaxed trot on a longe line without collection is initially recommended, with a very gradual and consistent increase in exercise every day if possible.[15,178] Advancing the horse too quickly often results in an episode of rhabdomyolysis and repeated frustration for the owner. Work can usually begin under saddle after 3 weeks of groundwork and can gradually be increased. It is very common to have subclinical elevations in CK activity when exercise is reintroduced, and a return to normal levels often requires 4 to 6 weeks of gradual exercise.[187] Keeping horses with PSSM fit is important for prevention of further episodes of rhabdomyolysis.

42.7.6.10.2 ### DIETARY MANAGEMENT OF POLYSACCHARIDE STORAGE MYOPATHY

The dietary modifications for PSSM horses are designed to reduce the glucose load and provide fat as an alternate energy source. Anecdotally, owners report that this type of diet improves clinical signs of muscle pain, stiffness, and exercise tolerance in draft horses, warmbloods, quarter horses, and other breeds.[178,212] Dietary change appears to have less of an impact on alleviating gait changes such as shivers.[44] The value of low-starch, high-fat diets in reducing exercise-induced muscle damage has been demonstrated only under controlled experimental conditions in quarter horses.[187] In PSSM quarter horses with increased sensitivity to insulin, dropping dietary starch to less than 10% of daily digestible energy and increasing dietary fat to 13% of daily digestible energy resulted in normal serum CK activity 4 hours postexercise during a 6-week trial. Provision of similar fat content and higher starch content resulted in increased serum CK activity in the most severely clinically affected horses. The beneficial effect of the low-starch, high-fat diet in this study (Re-Leve) appears to result from decreased glucose uptake into muscle cells and provision of more plasma free fatty acids in muscle fibers for use during aerobic exercise.[187] Quarter horses naturally have very little lipid stored within muscle fibers, and provision of free fatty acids may overcome the disruption in energy metabolism that appears to occur in PSSM quarter horses during aerobic exercise.[187,211] Studies clearly show, however, that these dietary changes alone are not beneficial, and an exercise program must be instituted for PSSM horses to show clinical improvement.[178] Further controlled experimental studies of the physiologic effect of low-starch, high-fat diets are necessary in other

breeds of horses with PSSM to determine how and if they truly have a beneficial effect. Anecdotally, some horses appear to have an increased incidence of rhabdomyolysis when on lush pasture. Therefore it seems reasonable to limit exposure to lush pastures. Hay that has a moderate to low content of soluble sugars and nonfermentable starch and fewer gluconeogenic amino acids would seem the best choice for PSSM horses. This includes second cutting of grass hay, brome hay, or oat hay.

The caloric needs of the horse should first be assessed in order to determine the amount of hay as well as low-starch, high-fat concentrates the horse requires. Provision of excessive calories in the form of fat to overweight horses is detrimental. For overweight horses, restricting hay to 1% to 1.5% of body weight and limiting access to pasture grass while increasing daily exercise are recommended. In addition, selection of a low-starch, fat-supplemented feed that is particularly high in dietary fiber may be the best means of providing dietary fat without causing excessive weight gain. Many low-starch high-fat diets are available for horses. The most important dietary principle appears to be that of the total daily calories required (digestible energy [DE]), less than 10% should be supplied by starch and at least 13% supplied by fat. Some authors recommend that 20% of daily caloric intake be supplied by fat (0.5 kg of fat) based on clinical experiences,[212] whereas others report improvement in clinical signs when 10% to 15% of DE is supplied as fat.[178,187,213] There is a great deal of variation in individual tolerance to dietary starch, however; horses with more severe clinical signs of PSSM appear to require the greatest restriction in starch intake.

1416

1417

42.7.6.11

Recurrent Exertional Rhabdomyolysis

Recurrent episodes of muscle stiffness, sweating, muscle contractures, and reluctance to move occur commonly in racing thoroughbreds, standardbreds, and Arabian horses. Many of these horses likely have tying-up as a result of a defect in the regulation of muscle contraction termed *recurrent exertional rhabdomyolysis* (RER).

42.7.6.12

Epidemiology and Genetics

Most studies show that approximately 5% of thoroughbred horses develop signs of muscle pain and cramping during a racing or polo season.[173,176,177,214] Approximately 75% of thoroughbred racehorses with RER have at least four episodes of rhabdomyolysis and 25% have more than 10 episodes in a 4-month racing season.[214] One predisposing factor for RER appears to be inheritance of susceptibility to developing exercise-induced episodes of rhabdomyolysis.[179,215] Analysis of pedigrees of thoroughbred horses from across the United States suggests that RER is an autosomal dominant trait. Furthermore, subsequent breeding trials confirm that the abnormal contracture test is inherited in an autosomal dominant fashion.[179]

Predisposing environmental factors that trigger rhabdomyolysis in susceptible horses include gender, temperament, diet, exercise duration and intensity, excitement, and lameness.[176,214] Females are most commonly affected by RER (67% female; 33% male), particularly those that are 2 years old and in race training.[214] Nervous horses are five times more likely to develop RER, and horses with lameness are four times more likely to tie up. Susceptible horses receiving more than 5 kg of sweet feed are more likely to develop rhabdomyolysis than those receiving 2.5 kg of sweet feed per day.[189,190]

42.7.6.13

42.7.6.13

Diagnosis

RER affects a specific subset of thoroughbred and likely standardbred and Arabian horses with intermittent episodes of exercise-induced rhabdomyolysis. These horses have increased numbers of centrally located nuclei in muscle biopsy samples and normal muscle glycogen staining (see Fig. 42-8).[14] In addition, RER is characterized by abnormal sensitivity of intact muscle bundles to contractures induced by caffeine or halothane in the muscle bath.[26,28,216] Although studies of muscle contraction indicate similarities to MH in swine, biochemical studies of isolated muscle cell membranes have not identified a similar defect in the function of the calcium-release channel in horses with RER.[156] Many thoroughbreds with RER have developed rhabdomyolysis under halothane anesthesia.[162,217]

42.7.6.14

Clinical Signs

Episodes often occur in horses once they become fit and are frequently associated with excitement at the time of exercise. In thoroughbreds, rhabdomyolysis occurs most frequently during training when horses are held to a slow gallop.[214] In standardbreds, rhabdomyolysis often occurs 15 to 30 minutes into slow jogging.[9] A history of poor performance and elevated serum AST and CK may be the only presenting complaints in some horses. Older thoroughbreds used as riding horses may have very intermittent episodes of rhabdomyolysis associated with lay-ups of fit horses or with the steeplechase in 3-day events. Muscle stiffness and reluctance to collect may be present on a continual basis between episodes in some of these older horses. Arabian horses often develop clinical signs with little exertion, frequently in association with excitement.

42.7.6.15

Prevention

RER appears to be an inherited disorder that is expressed when horses are subjected to the stress and rigors of training, particularly at a young age. Prevention of further episodes of RER in susceptible horses includes adhering to standardized daily routines and providing an environment that minimizes stress. This should include desensitizing horses to stressful situations, moving the stall to a quiet area of the barn, performing regular turnout, and so on. Daily exercise is essential, whether in the form of turnout, longing, or riding.

In the past, horses have been box-stall rested for several weeks after an episode of RER. It is my opinion that this is counterproductive and increases the likelihood that the horse will develop RER when put back into training. The initial muscle pain usually subsides within 24 hours of acute RER, and daily turnout in a small paddock can be provided at this time. Subsequently a gradual return to performance is recommended once serum CK is close to normal range.

The diet should be adjusted to include a balanced vitamin and mineral supplement, high-quality hay, and a minimum of carbohydrates (<2.5 kg) such as grain and sweet feed. Additional dietary fat supplements are helpful to maintain weight in nervous horses without providing excessive carbohydrates. In hard keepers or horses in heavy work, corn oil and rice bran added to the diet may not be adequate to maintain weight. In such cases new commercial feeds that are low in starch and high in fiber, designed for horses with RER, are helpful to maintain weight but avoid rhabdomyolysis.[190] The use of low doses of acepromazine tranquilizers (e.g., a dosage rate of approximately 0.005 to 0.01 mg/kg) 30 minutes before exercise in excitable horses is believed to help some horses.

Dantrolene 2 to 4 mg/kg PO given 1 hour before exercise in fasted horses is effective in preventing RER

Dantrolene 2 to 4 mg/kg PO given 1 hour before exercise in fasted horses is effective in preventing RER.[153,218] Dantrolene decreases the release of calcium from the sarcoplasmic reticulum during contraction. Phenytoin has also been advocated as a treatment for horses with RER. Doses are adjusted in horses to maintain serum levels of 8 to 10 μ/mL. Initial dosages begin at 6 to 8 mg/kg PO for 3 to 5 days. Doses can be increased by 1-mg/kg increments every 3 days until rhabdomyolysis is prevented but should be cut back if horses appear drowsy.[216] If possible, serum phenytoin concentrations should be assessed regularly at the initiation of treatment. Phenytoin acts on a number of ion channels within muscle and nerves including sodium and calcium channels. Unfortunately, long-term treatment with dantrolene or phenytoin is expensive, and efficacy has not been established.

42.7.7 HEREDITARY AND CONGENITAL MYOPATHIES

STEPHANIE J. VALBERG

42.7.8 MITOCHONDRIAL MYOPATHY

A deficiency of complex 1, the first step in the mitochondrial respiratory chain, has been identified in a young Arabian filly that was presented for veterinary attention with clinical signs similar to those of ER.[219] In contrast to cases of ER, however, this horse showed no changes in serum CK after exercise. A marked lactic acidosis developed even with light exercise, and maximum oxygen consumption was drastically reduced, resulting in marked exercise intolerance. Histopathologic evaluation of muscle biopsy samples showed an abnormal increase in mitochondrial density, and biochemical analyses revealed a complex 1 deficiency. The horse has shown slowly progressive signs of muscle atrophy but has otherwise remained healthy at rest.

1417

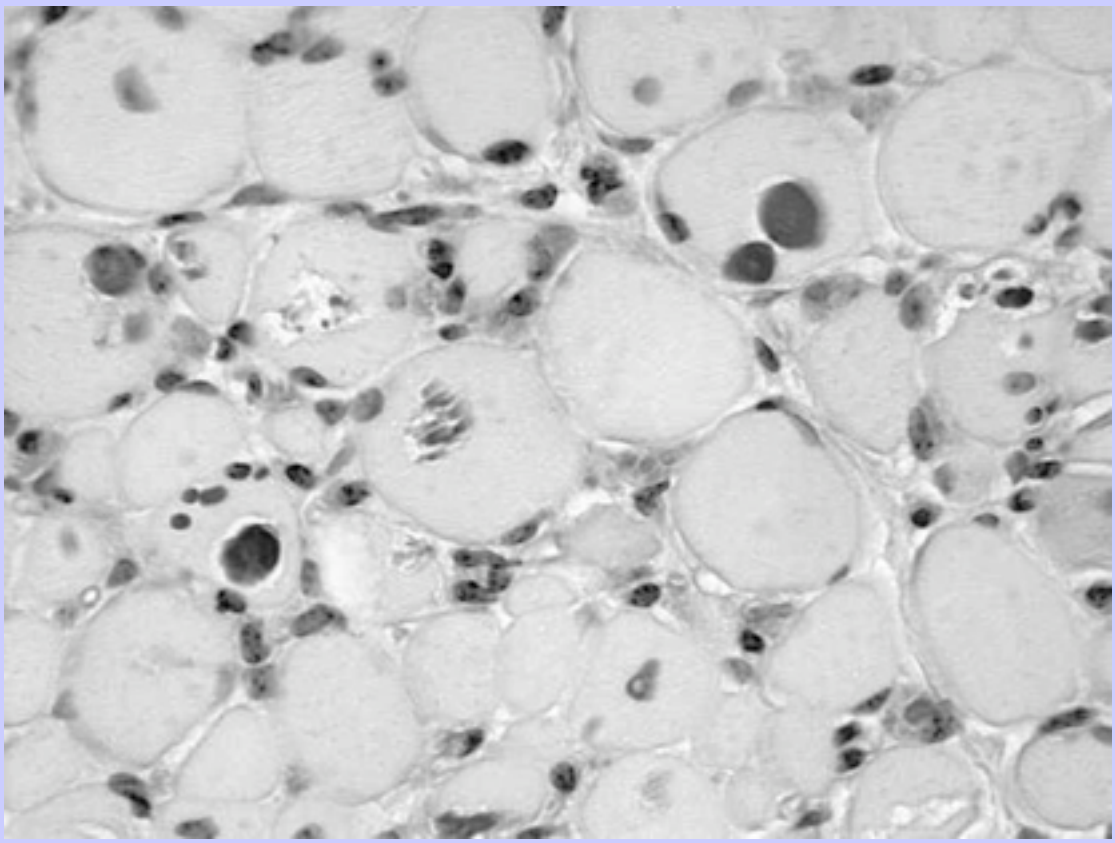
1418

42.7.9 GLYCOGEN BRANCHING ENZYME DEFICIENCY

Glycogen branching enzyme deficiency (GBED) is a glycogen storage disorder causing abortion, seizures, and muscle weakness in quarter horse—related breeds.[220–222] It is a glycogen storage disorder separate from PSSM. GBED is caused by a nonsense mutation in exon 1 of the *GBE1* gene at codon 102 that introduces a premature stop codon.[222] Nine percent of the breed are carriers of this autosomal recessive mutation, and 3% of abortions are attributed to this disease in quarter horses.[220] Most foals diagnosed with GBED are presented with hypothermia, weakness, and flexural deformities of all limbs at 1 day of age. Ventilatory failure may also be a presenting sign, in addition to recurrent hypoglycemia and collapse. All foals have died either from euthanasia because of muscle weakness or suddenly because of apparent cardiac arrhythmia. Persistent leukopenia, intermittent hypoglycemia, and high serum CK (1000 to 15,000 U/L), AST, and γ-glutamyltransferase (GGT) activities are features of affected foals. Gross postmortem changes are not evident, and routine hematoxylin and eosin stains of tissues may be normal or show basophilic inclusions in skeletal muscle and cardiac tissues. Frozen sections of muscle, heart, and liver show a notable lack of normal PAS staining for glycogen as well as abnormal PAS-positive globular or crystalline intracellular inclusions (Fig. 42-19). Branching enzyme activity is minimal in skeletal and cardiac muscle as well as liver. A diagnosis is best obtained by confirming the presence of the genetic mutation in tissue samples or by identifying typical PAS-positive inclusions in muscle or cardiac samples.[220–222]

Fig. 42-19 Periodic acid—Schiff (PAS) stain of skeletal muscle from a foal with glycogen branching enzyme deficiency. Note the lack of

normal diffuse magenta staining for glycogen and the presence of globular and crystalline PAS-positive inclusions.



42.7.10 PHOSPHORYLASE DEFICIENCY IN CHAROLAIS CATTLE

A deficiency of the enzyme phosphorylase (McArdle's disease) has been identified in Charolais cattle in the United States and New Zealand.[223–226] Affected animals had exercise intolerance and often collapsed when forced to exercise. Serum CK was elevated in all affected animals, and one calf had severe rhabdomyolysis clinically resembling white muscle disease. Screening for myophosphorylase can be performed by histochemical staining for phosphorylase activity in frozen sections of muscle biopsies. Confirmation of the autosomal recessive disease is obtained by biochemical analyses or identification of the C-to-T substitution, which changes an encoded arginine (CGG) to tryptophan (TGG). This disease should be considered as a differential diagnosis for white muscle disease in Charolais cattle that are found to have normal vitamin E and selenium status.

42.7.11 MYOFIBER HYPERPLASIA

Myofiber hyperplasia is an inherited condition occurring in certain breeds of cattle and rarely in sheep, characterized by a disproportionate increase in skeletal muscle mass. Synonyms for the disorder include *double muscling, doppellender,* and *culard*.[227–229] The condition is well recognized in cattle and is most commonly seen in the Belgian Blue, Piedmont, and South Devon breeds. The term *double muscling* is misleading because there is no increase in the number of muscle groups. The increase in muscle mass is the result of hyperplastic type 2B myocytes, with a reduction in the number of types 1 and 2A myocytes. The degree of myofiber hyperplasia varies among affected animals. Increases in muscle size are most evident in hindlimbs, forelimbs, lumbar area, and neck; well-defined grooving often separates muscle groups (similar to the muscle definition seen in human bodybuilders). Muscle/bone ratio is increased; decreased amounts of body fat yield a leaner carcass at slaughter. Affected animals show increased weight gains over similarly treated unaffected herdmates. The skin of affected animals is thinner than that of normal herdmates.

Myofiber hyperplasia appears to be inherited as a single major autosomal locus with several modifiers of phenotypic expression resulting in incomplete penetrance. In Belgian Blue and Piedmont cattle an 11 nucleotide deletion and a missense mutation, respectively, have been identified in the myostatin gene. Myostatin is a transforming growth factor that is a negative regulator of skeletal muscle mass during development. Heterozygotes for the gene often show some degree of muscle hyperplasia. Clinical problems encountered as a result of this disorder include dystocia in dams producing affected calves and oral anomalies such as hypertrophy of the tongue, brachygnathism, and prognathism; there is also a very high incidence of inherited spastic paresis (Elso heel) in affected cattle.

A genetic disorder that results in myofiber hyperplasia has also been identified in sheep.[230]

43.1.1 NONPATHOGENIC INFERTILITY

43.1.1.1 THE BREEDING SEASON

43.1.1.1.1 Mares

The mare is a seasonally polyestrous animal, breeding during seasons of long day length. Annual breeding and nonbreeding seasons are divided by fall and spring transitional periods, which are characterized by erratic reproductive behavior and irregular estrous cycles.

43.1.1.1.2 Clinical Signs

During the breeding season, mares ovulate every 21 days (range 19 to 22 days).[1] Estrus (5 to 7 days, but variable) is characterized by the presence of an ovarian follicle, serum progesterone level of less than 1 ng/mL, and sexual receptivity. During estrus the cervix is palpably relaxed and the uterus is edematous. One or two follicular waves occur per cycle, and preovulatory follicles are 45 to 60 mm in diameter, often with a cone-shaped appearance on ultrasonography.[2] Ovulation occurs 24 to 48 hours before the end of estrus and may be accompanied by ovarian sensitivity.[1] The ruptured follicle is replaced by a corpus luteum (CL). Diestrus (luteal phase) is predictable in length because regression of the CL, caused by release of endometrial prostaglandin $F_{2\alpha}$ ($PGF_{2\alpha}$), occurs 14 to 15 days after ovulation.[3] During diestrus and early pregnancy the cervix is tight and the uterus is firm and tubular. Diestrous ovulations occur and may be fertile.[4] First postpartum estrus (“foal heat”) begins in the week after foaling, and ovulation occurs in most mares 7 to 15 days postpartum.

43.1.1.2

Ruminants

43.1.1.2.1

COWS

Cows are polyestrous, but seasonal differences in fertility may be caused by climate. The estrous cycle averages 21 days (range 17 to 25 days), and the duration of estrus averages 12 to 16 hours (range 6 to 24 hours). Cows are unique among domestic animals in that they ovulate spontaneously after the end of estrus, 24 to 30 hours after the beginning of estrus.[5]

In the absence of a bull, estrus can be detected in cows by their homosexual (bisexual) activity. Cows that stand to be mounted by another cow are in estrus (standing heat). Secondary signs that may be helpful in detecting estrus include restlessness and increased activity, vulvar hyperemia and edema, and a clear mucous discharge. Errors in heat detection are a common cause of infertility on large dairy farms.[6] The optimum time for insemination of cows is between 16 and 24 hours after the onset of estrus. Insemination of cows on the basis of standing to be mounted results in a higher pregnancy rate than if it is based on secondary signs of estrus.[7] Well-managed dairy cows with uncomplicated periparturient experiences may ovulate approximately 20 to 25 days after calving, whereas beef cows with nursing calves usually do not ovulate until 40 or more days after calving. The presence of the calf appears to be responsible for the difference in return to cyclicity.[8]

43.1.1.2.2

SHEEP

Coarse-wooled breeds of ewes are seasonally polyestrous during the autumn and winter (short photoperiod) in temperate climates. Ovulation can be induced in seasonally anestrous ewes by artificial simulation of day length and temperatures characteristic of autumn (reduced photoperiod and reduced ambient temperature), but the long latency period required for response to manipulation of light and temperature makes the procedure impractical. Ewes of fine-wooled breeds may be polyestrous throughout the year if adequately nourished. The estrous cycle of ewes averages 17 days (range 14 to 19 days), and the duration of estrus averages 36 hours. Ovulation occurs spontaneously 24 hours after the onset of estrus. Ewes display few, if any, signs of estrus unless a male is present. The primary signs of estrus include seeking the ram and standing for mating. Secondary signs include restlessness and rapid tail switching; vulvar edema and discharge of clear cervical mucus may be observed occasionally. Lambing ordinarily occurs during the anestrous season; therefore ewes do not return to estrus until the next breeding season.[5]

43.1.1.2.3

GOATS

Does in temperate climates are seasonally polyestrous from late summer until early spring (short photoperiod). Onset of the breeding season in yearling does can be advanced by exposing them to 19 hours of artificial light per day for 70 days beginning in mid to late winter. Termination of artificial light results in a relative decrease in day length and stimulation of estrus and ovulation.[5] Alternatively, the breeding season may be hastened by exposing does to 14 to 18 hours of light per day for 3 months, followed by a reduction to 6 hours of light per day.[7] The estrous cycle averages 21 days, and estrus lasts 18 to 36 hours. 1419
Ovulation occurs spontaneously 24 hours after the onset of estrus. An intact male or male pheromone is 1420
usually necessary for estrous detection. The primary signs of estrus are seeking the buck and standing for

service. Secondary signs of estrus in does include rapid tail switching, restlessness, increased frequency of urination and vocalization, transient decrease in appetite and milk production, and edema and hyperemia of the vulva. As in sheep, parturition takes place during the anestrous season, and return to cyclicity in does is delayed until the next breeding season.[5]

43.1.1.2.4 CAMELIDS

South American camelids bred in North America are nonseasonal. In keeping with management decisions, they are often bred in a seasonal manner to avoid having newborn crias during the hottest or coldest months of the year. Some consider the South American camelids to be polyestrous, whereas others argue that they do not have a true estrous cycle.[9] These discrepancies arise from the fact that camelids are induced ovulators. Cyclic ovarian activity (e.g., transition from estrus to diestrus) is caused by coital activity. Unbred female camelids essentially exhibit estrous behavior continually, with perhaps short, occasional, unpredictive intervals of 1 to 2 days of decreased receptivity. Follicular waves in alpacas and llamas last around 17 days. Small follicles (≤3 mm) are always present on the surface of the ovaries. After recruitment, follicles grow to approximately 5 mm in size. Dominance is established when one of the follicles reaches the size of 6 mm, and the female will show signs of receptivity to the male as long as a dominant follicle is present. The sizes of preovulatory follicles are 9 to 13 mm and 8 to 12 mm in the llama and alpaca, respectively. Females maintain fertile, dominant follicles for an average of 8 days before undergoing regression. Usually the next follicular wave has already produced the next dominant follicle before the previous preovulatory follicle begins to regress. For this reason, the female camelid usually maintains estrous behavior continually until she is mated.[9]

43.2 CYSTIC FOLLICULAR DEGENERATION

43.2.1 Cows

Ovarian cysts are follicle-like ovarian structures that arise because of failure of ovulation.[5] They are usually larger than 25 mm in diameter and persist in the absence of a CL for 10 days or more. Follicular cysts have thin walls and may be single, multiple, or multilocular structures on one or both ovaries. Partially luteinized cysts tend to be single, unilateral structures with thicker walls because of the presence of luteal tissue.

The mechanism by which ovulation fails and cysts develop is not known. Failure of ovulation may result from inadequate release of gonadotropins or ovarian dysfunction. Increased stress of conditions such as retained placenta, metritis, and hypocalcemia around the time of calving and postpartum ketosis have been associated with an increased prevalence of cystic follicular degeneration (CFD), as has a hereditary predisposition.[10]

43.2.1.1 Clinical Signs and Diagnosis

Approximately 70% to 80% of cows affected by CFD are anestrus, whereas 20% to 30% display frequent or intense estrus (nymphomania). Cystic ovarian disease affects 10% to 30% of dairy cows. The condition is rare in commercial beef cows because of rigid culling for reproductive failure.

The physical appearance of cows with CFD depends on the duration of the condition. No changes are apparent after a short time, but in long-standing cases relaxation of the pelvic ligaments may result in prominence of the tailhead and masculine characteristics such as a crested neck.

The diagnosis of CFD is based on an accurate history and clinical examination. A history of constant or frequent estrus, short interestrous intervals, or anestrus may suggest CFD. Examination of the ovaries by palpation per rectum reveals the presence of enlarged fluid-filled structures raised above the surface of the ovary that greatly increase total ovarian size. Ovarian cysts are larger (>25 mm) than preovulatory follicles (15 to 25 mm). Differentiation between a single large cyst and several smaller cysts on the same ovary may not be possible, nor may be recognition of the presence of partially luteinized cysts (based on peripheral progesterone concentrations) unless ultrasonography is used. Ovarian cysts appear to be dynamic structures; those that develop early in the postpartum period may regress without treatment, and a normal estrous cycle may follow, or another cystic structure may develop.

During palpation of the ovaries, several normal structures may complicate the diagnosis of CFD. Normal preovulatory follicles may approach 25 mm in diameter and have palpable characteristics similar to those of small cysts. During the follicular phase of the estrous cycle, however, the uterus responds to palpation by becoming more turgid, whereas the uterus of a cow with CFD is typically flaccid and unresponsive. In neglected cases of CFD, mucometra may develop and must be differentiated from pregnancy. During the first 5 to 7 days of the estrous cycle, the developing CL may be smooth and soft and is commonly mistaken for an ovarian cyst. More mature CLs are solid and liver-like in consistency, often feature a palpable ovulatory papilla at the apex, and are more easily differentiated from ovarian cysts. However, 10% to 20% of mature CLs may lack an ovulatory papilla, making them more easily confused with ovarian cysts. Ultrasonography is generally more accurate in identifying subtle structural differences than transrectal palpation. Salpingitis, hydrosalpinx, oophoritis, ovarian abscesses, ovarian neoplasms, and cysts of the fimbria are other causes of enlargement of the ovary and surrounding structures that must be differentiated from ovarian cysts.[11]

Histories that may erroneously suggest CFD include apparently short interestrous intervals because of inaccurate detection of estrus.[12] Oxytocin administered to stimulate milk letdown may result in short interestrous intervals and suggest CFD. The estrous cycle may be shortened by administering 100 IU of oxytocin per day on days 2 through 6[13] or on days 3 through 7 or 8.[14] Heifers treated with 100 IU of oxytocin per day returned to estrus in an average of 12.9 days versus 20.3 days in untreated controls.

43.2.1.2

Clinical Pathology

Plasma progesterone concentrations are low in cows with follicular cysts. Partial luteinization may occur, and progesterone concentrations may increase over time but remain lower than those of cows with normal CLs. Estrogen concentrations in the plasma of cows with CFD are variable.

43.2.1.3

Treatment and Prognosis

The goal in treating CFD is to induce luteinization of the cyst and reestablish normal estrous cycles. Several methods have been recommended.

43.2.1.3.1

SPONTANEOUS RECOVERY

Spontaneous recovery from CFD occurs in up to 60% of cows that develop CFD before the first ovulation after calving but in only approximately 20% of cases that develop after the first postpartum ovulation. Evaluation of therapeutic agents for CFD may be confounded by spontaneous recovery.

43.2.1.3.2

LUTEINIZING HORMONE

Recommended doses of human chorionic gonadotropin (hCG) range from 5000 IU either intravenously (IV) or intramuscularly (IM) to 10,000 IU IM. Of cows treated with a single dose of hCG, 65% to 80% establish a normal estrous cycle within 3 to 4 weeks; a second or third dose may be required in cows that do not respond after 3 to 4 weeks or in cases in which nymphomania persists. Anaphylaxis after repeated treatments with a larger protein hormone such as hCG can occur. Antibodies to hCG may reduce the effectiveness of sequential treatments. Therapeutic response, both endocrinologically and clinically, is essentially equivalent between hCG and gonadotropin-releasing hormone (GnRH). The practical disadvantage of hCG is its higher price.

1420
1421

43.2.1.3.3

GONADOTROPIN-RELEASING HORMONE

Currently the most common treatment for ovarian cysts, especially follicular cysts, is an injection of GnRH (100 mcg IM). Cows responding to this treatment have an average interval to estrus of one estrous cycle or 18 to 24 days. The treatment to breeding interval can be shortened by administering GnRH at the time of diagnosis, followed by a luteolytic dose of prostaglandin 10 days to 2 weeks later. With this regimen it is not critical whether the cyst is follicular or luteal or even whether it is a misdiagnosed large, smooth CL with or without a fluid-filled central cavity. Most veterinarians agree that accurate differential diagnosis by rectal palpation among follicular cysts, luteal cysts, and some CLs can be a problem.

43.2.1.3.4

PROSTAGLANDIN $F_{2\alpha}$

Luteal-type cysts can be treated with the luteolytic activity of PGF. The advantage is the quicker return to estrus for those cows able to respond and the lower cost of PGF. Cysts that luteinize in response to GnRH regress at a time similar to that of normal CLs. Treatment with PGF may be used to reduce the interval from treatment with GnRH to estrus from 18 to 24 days to an average of 12 to 14 days by administering PGF 9 days after GnRH. Most clinicians are only approximately 50% accurate in determining the degree of luteinization of cysts by palpation per rectum; therefore measurement of concentrations of progesterone in milk or of plasma from affected cows allows the selection of GnRH or hCG for treatment of follicular cysts and PGF for the treatment of luteinized cysts. Ultrasonography can also be used to make an accurate diagnosis.[15]

43.2.1.3.5

MANUAL RUPTURE

Thin-walled follicular cysts may be inadvertently ruptured during examination of the ovaries, and some practitioners may intentionally attempt cyst rupture. Recovery rates after manual rupture have rarely been studied in well-designed controlled experiments but are generally within the range reported for spontaneous recovery. Deliberate manual rupture of ovarian cysts is considered an obsolete form of treatment by some veterinary clinicians, but others routinely use the procedure—especially as an initial treatment for cysts found during the voluntary waiting period. Manual rupture of cysts may be followed by hemorrhage and adhesions between the ovary and surrounding structures. These complications appear to be much more common with use of digital pressure to enucleate CLs than with manual rupture of ovarian cysts.

43.2.2 Ewes and Does

Cystic ovaries appear to be more common in goats than in sheep. In one study 12% of goats had cystic ovaries when examined at a slaughterhouse.[16] The condition is often overdiagnosed by owners observing nymphomania. Treatment typically consists of administering exogenous ovulation-hastening drugs (hCG and GnRH).[17] LH surge is noted usually within 2 hours of GnRH administration. PGF may be administered 10 days later to bring the doe into heat (55 hours after PGF).

43.2.3 Camelids

Hemorrhagic follicles are observed in nonbred llamas and usually regress within 22 days.[18] Follicles larger than 12 mm are considered by some authors as pathologic cysts. These structures may, however, be anovulatory follicles. They may have a negative influence on the emergence of other follicular waves, but this influence seems to last for only approximately 8 days.[9,19]

43.3 POOR NUTRITION

As with other species, poor body condition, depressed energy intake, and decreased vitamin and mineral intake suppress reproductive activity in ewes and does. Lowered energy balance results in poor or weak signs of estrus, depressed ovulation, abnormal cycle, and delayed puberty. Deficiencies in energy, protein, vitamins A and E, phosphorus, and many trace minerals (iodine, copper) are commonly seen. These deficiencies are most commonly associated with irregular estrous cycles.

43.4 PLANT TOXICITY

43.4.1 Ergot Alkaloids

The consumption of fescue infected with *Neotyphodium coenophialum*, is associated with decreased reproductive efficiency. The ergot alkaloids have been shown to affect prolactin production in ewes and to increase the interval from introduction of the ram to conception.

43.4.2 Estrogen-Producing Plants

Sheep appear to be sensitive to the effects of phytoestrogens. Clinical observations include infertility, irregular and prolonged heat cycles, lowered conception rates, and early embryonic death.

43.5 HEAT STRESS

Fertility in lactating cows is decreased during the hot seasons of the year. Heat stress may cause decreased estrous detection, impair follicular development, disrupt function of the reproductive tract, affect oocyte competence, and lead to early embryonic death. Embryos develop resistance to heat shock as they age. Bovine morulae to blastocyst stages are unaffected by heat shock.[19a]

43.6 ANESTRUS

Anestrus, may be defined as ovarian inactivity. The causes of anestrus are multiple and include diseases of the reproductive and other systems. In addition, the problem is complicated by management factors that cause estrus to pass undetected, even though the animal's estrous cycles and estrous behavior are normal. Common causes of anestrus in mares are summarized in Table 43-1.

43.7 MARES

43.7.1 PUBERTY

The mare likely undergoes puberty between the ages of 12 and 24 months. Because the horse is not an agricultural production animal, there has been little interest in studying the onset of puberty as in other species, where hastening puberty increases production. Most mares are not bred until they are at least 3 years old, thus making prepubertal status an unlikely differential diagnosis for infertility.

43.8 SEASONAL ANESTRUS

43.8.1 Clinical Signs and Diagnosis

1421 1423

The mare is a seasonally polyestrous animal, showing anestrus during the shorter days of the year and cycling regularly during the longer days. Length of anestrus varies from one to several months, although some mares, particularly in the tropics, may cycle year round.[20] In California, Australia, and South Africa 18% to 25% of mares cycle year round.[1,21–23] Anestrous mares may be indifferent to teasing and do not show regular estrous behavior. Ovaries are small and firm on palpation, and the uterus is flaccid with a thin endometrium. The cervix has mild tone and may be indistinct. On speculum examination of the vagina, the vaginal mucosa is pale and dry, and the cervix usually appears closed but is occasionally open or may be easily opened. Mares that experience seasonal anestrus will go through a transition period in late winter and early spring, characterized by the development of waves of antral follicles that regress without ovulation because the ovulatory surge of luteinizing hormone (LH) is absent.[23] Transitional mares exhibit signs of estrus, including clitoral “winking,” tail flagging, and urinating in the presence of the stallion. Eventually, increasing LH concentration coincides with a large follicle, resulting in ovulation. After the first ovulation of the season, the mare will continue to ovulate on successive estrous cycles. A transition period is also observed during the fall as the mare changes from a polyestrous condition to the winter anestrus. Differential diagnoses for seasonal anestrus and transitional mares are listed in Table 43-1.

Table 43-1 Differential Diagnosis of Anestrus in Mares

Cause	Uterus	Cervix	Ovaries	Peripheral Progesterone	Season	Other Laboratory Tests	Treatment
Pregnancy	Increased tone during early pregnancy; enlarged; positive signs of pregnancy by palpation or ultrasound	Tightly closed	Normal size during early pregnancy; out of reach of examiner in late stages	Elevated throughout pregnancy until just before term	Any season; may be more common in spring and summer	Equine chorionic gonadotropin; Cuboni test	Usually none required; therapeutic abortion if mismated
Prolonged diestrus	Normal size, increased tone and tubularity; may be similar to early pregnancy	Tightly closed	Normal size; prolonged corpus luteum is embedded within ovary	Elevated throughout prolonged lifespan (30 to 90 days)	Any season; may be more common in summer		PGF
Seasonal anestrus	Normal size; flaccid; difficult to palpate	Varies from tightly closed to open	Both are small and firm, may or may not have small follicles	Low until first corpus luteum develops	Late autumn, winter, early spring		Artificial lights; wait for normal breeding season
Unobserved estrus	Normal size	Characteristic cyclic changes; relaxed and open during estrus	Development of one (or more) follicles; ovulation	Elevated for ~14 days; low for ~7 days	Spring, summer, autumn		Improve management; tease with another stallion; sequential examinations; PGF
Pyometra	Variable enlargement	May be open, closed, or stenotic; purulent discharge may be present	Normal size, follicular development may be present	Erratic profiles; some are elevated for prolonged periods, others may have luteal regression	Any season	Endometrial cytology; bacterial culture; antibiotic sensitivity	Drain; systemic antibiotics; PGF
Undernutrition	Normal size	Varies from tightly closed to open; no cyclic changes	Bilaterally small and firm	Low	Any season	Hematology; clinical chemistry as indicated; fecal flotation	Improve nutritional status; parasite control; treat concurrent diseases

Granulosa-theca cell tumor	Normal size	Varies	One enlarged, multicystic; other small and atrophic	Low	Any season	Peripheral inhibin concentrations are elevated in ~90% and testosterone in ~50% of mares with granulosa-theca cell tumor	Surgical removal of neoplastic ovary
Gonadal dysgenesis	Small	Varies	Small, firm, atrophic	Low	Any season	Karyotype	None

PGF, Prostaglandin F.

43.8.2 Treatment and Prognosis

As day length increases, most mares ovulate and begin regular cyclicity without treatment. Methods to advance the onset of regular ovulatory periods are discussed in the following sections.

43.8.2.1 ARTIFICIAL LIGHTING

The vernal transition can be moved but not shortened beyond its physiologic length of 6 to 8 weeks by exposure of mares to artificial light. A common artificial lighting regimen is to expose the mares to 16 hours of light and 8 hours of dark by extending the photoperiod in the evening starting in late November to initiate ovulation by February (in the Northern Hemisphere). Light should be added to the end of the day, or split between the beginning and end of the day, as opposed to adding light only at the beginning of the day.[6] An alternative regimen is to expose mares to 1 hour of artificial light 9.5 to 10.5 hours after the onset of darkness.[24] Use of one 200-watt incandescent bulb or two 40-watt fluorescent tubes at a height of 7 to 8 feet in a 12- by 12-ft box stall has been recommended.[25] Paddock lighting has been described.[5]

43.8.2.2 GONADOTROPIN-RELEASING HORMONE

Treatment with GnRH or a GnRH analogue for mares in anestrus or spring transition has been shown to induce ovulation.[26–30] Twice-daily injections of a GnRH agonist induced ovulation in a majority of mares within 2 to 3 weeks.[30] Mares that are in deep anestrus (January and February, Northern Hemisphere) can be expected to return to anestrus after treatment.

43.8.2.3 DOPAMINE ANTAGONISTS

Domperidone and sulpiride have been reported to stimulate follicular activity and advance the first ovulation of the year in seasonally anestrous mares.[31,32] However, the efficacy of dopamine antagonists in advancing follicular growth and ovulation in anestrous mares has recently been questioned, and it has been suggested that adjustments in light and climactic conditions may influence the efficacy of the treatment.[33,34]

43.8.2.4 STEROIDS

Exogenous progestins suppress the release of LH from the anterior pituitary and may be used for estrous regulation during the vernal transition. After treatment of mares for 10 to 14 days, withdrawal of progestin may result in LH release from the pituitary and estrus beginning in 4 to 5 days, with ovulation within 10 days after cessation of treatment. Mares should be in mid to late transition and have a follicle at least 25 mm in size to respond to treatment. Progestins will not induce estrus or ovulation in anestrous mares.[35] The recommended dose of progesterone in oil is 150 to 300 mg daily by intramuscular injection. The synthetic progestin, altrenogest, is administered orally (PO) at 0.044 mg/kg daily. Progestins may be used in combination with extended photoperiod and gonadotropins. Products that are ineffective or unavailable include repositol progesterone, melengestrol acetate, chlormadinone acetate, proligestone, medroxyprogesterone acetate, hydroxyprogesterone acetate, and norgestomet implants.

Synchronization of the first ovulation (or any ovulation during the cyclic season) can be accomplished by the administration of a combination of progesterone in oil (150 mg/day IM) and estradiol-17β (10 mg/day IM) once daily for 10 days.[36] Treatment is most effective if given after mares have been under lights for 45 to 60 days. $PGF_{2\alpha}$ should be given on the last day of steroid treatment. Treated mares will ovulate within 8 to 10 days after the last treatment.

43.8.2.5 GONADOTROPINS

At a dose of 2500 to 3000 IU, hCG may induce ovulation within 48 hours when administered to a mare with a follicle larger than 35 mm in diameter[37] and may reduce time to first ovulaton in transitional mares, particularly when used in combination with lights and/or progesterone treatment. Ovulation response here is less predictable than that induced with hCG during the breeding season.

43.8.2.6 FOLLICULAR ASPIRATION

Ultrasound-guided transvaginal follicular aspiration of follicles <35 mm has been shown to hasten the onset of cyclicity in transitional mares.[38] Follicular aspiration resulted in the formation of an active CL, and subsequent treatment with $PGF_{2\alpha}$ resulted in estrous behavior and ovulation of a dominant follicle.

43.9 PROLONGED LUTEAL PHASE AND PSEUDOPREGNANCY

Mares that experience embryonic loss in the presence of endometrial cups (days 35 to 150 of gestation) are said to be *pseudopregnant*, (*pseudopregnancy*, may also refer to that condition in which a conceptus was lost after maternal recognition of pregnancy and before the development of endometrial cups, resulting in prolonged luteal life). In spite of the loss of the fetus and placental tissue, endometrial cups remain in place and continue to secrete equine chorionic gonadotropin (eCG) for a similar period to that in a pregnant mare, to 100 to 150 days of gestation.[39] The primary and secondary CLs occasionally regress after embryonic loss[40] but usually remain during eCG secretion, maintaining high levels of peripheral progesterone.

43.9.1 Treatment and Prognosis

In untreated mares, cyclic activity is reestablished after the cessation of eCG secretion. Repeated daily injections of PGF products have been reported to cause luteal regression in pseudopregnant mares,[41] but only CLs older than 5 days respond to the treatment, which may prevent mares returning to estrus. Pregnancies have occurred in the face of high eCG,[42] but fertility of treated mares is usually low.

43.10 LACK OF BEHAVIORAL ESTRUS (SILENT ESTRUS)

Behavioral estrus may not be detected in otherwise normal mares as a result of inadequate estrous detection or a failure on the part of the mare to show obvious signs of estrus. The latter may occur in up to 15% of mares on well-managed farms.[43] Inadequate estrous detection may be a result of human apathy or ignorance or a result of using a low-libido or inexperienced stallion. Teasing mares as a group may make detection of estrus more difficult, especially for nervous mares, mares with foals, and mares of low social rank. Use of anabolic steroids may suppress behavioral estrus.

1423
1424

43.10.1 Clinical Signs and Diagnosis

The mare fails to show estrus on adequate teasing with a stallion. Differential diagnoses are listed in Table 43-2.

Table 43-2 Irregularities of the Equine Estrous Cycle: DifferentialDiagnosis

Etiology	Distinguishing Features
FAILURE TO CYCLE WITH LOW PROGESTERONE	
Winter anestrus	Season; inactive ovaries
Gonadal dysgenesis	Small, hard, inactive ovaries; karyotype; underdeveloped tubular tract; small body
Pituitary adenoma	Systemic signs; inactive ovaries
Granulosa-theca cell tumor	See prolonged or irregular behavioral estrus
Behavioral	Intimidated by stallion; recently foaled; low social rank
FAILURE TO CYCLE WITH HIGH PROGESTERONE	
Pregnancy	Presence of embryonic vesicle or fetus
Persistent CL	CL fails to regress; responds to PGF
Diestrous ovulation	CL immature at time of endogenous PGF; responds to exogenous PGF
Pseudopregnancy	Conceptus loss after maternal recognition of pregnancy; responds to exogenous PGF
Iatrogenic	History of exogenous progestin or nonsteroidal antiinflammatory drug administration
Pyometra	Uterus palpably enlarged
SHORT LUTEAL PHASE	
Uterine infection	Pyometra or endometritis causing premature endogenous PGF secretion
Systemic endotoxemia	Systemic signs; endotoxin-mediated release of endogenous PGF
Iatrogenic	History of uterine manipulation, infusion, invasive procedure, or exogenous PGF
PROLONGED OR IRREGULAR BEHAVIORAL ESTRUS	
Transitional period	Season, variable ovarian activity
Granulosa-theca cell tumor	Affected ovary large and multicystic, contralateral ovary small; elevated inhibin and/or testosterone; anestrus, nymphomaniac or stallion-like behavior
Gonadal dysgenesis	Occasionally irregular cyclicity; as above
Behavioral nymphomania	Otherwise normal mare
Normal mare	Mares in winter anestrus and pregnancy may show estrous signs

CL, Corpus luteum; *PGF*, prostaglandin $F_{2\alpha}$.

43.10.2 Treatment and Prognosis

Management should be examined to ensure a competent teasing routine. When approached by a stallion, mares in estrus stand still with ears held forward; they may elevate the tail, rhythmically evert the clitoris ("winking"), assume a squatting posture, urinate, and lean against the teasing chute toward the stallion. Mares that are not in estrus move about and hold their ears back; they may strike, kick, squeal, swish their tails, and forcefully void small amounts of urine. Experienced personnel should handle both stallion and mare. The teaser stallion should have adequate libido without being aggressive. Transrectal palpation and ultrasonography should supplement teasing. Some mares are indifferent to teasing, and records of sequential palpation must be relied on for breeding. Prostaglandins can be used to control estrus. Progesterone concentrations of less than 1 ng/mL are consistent with estrus but may also occur in anestrous mares. Mares that fail to show behavioral estrus should be bred by artificial insemination (AI) (if allowed by the breed register) or appropriate restraint used for natural cover.

43.11 BEHAVIORAL NYMPHOMANIA

Abnormal estrous behavior and aggression may be demonstrated by otherwise normal mares at any stage of the estrous cycle. Cause is unknown, although exaggerated response to ovarian steroids has been proposed.[44]

43.11.1 Clinical Signs and Diagnosis

Exaggerated signs of estrus occur, initially during estrus and then throughout the cycle. Mares may develop behavioral anomalies and become aggressive. Differential diagnoses are listed in Table 43-2. It is important to differentiate abnormal estrous behavior from unrelated behavioral problems.

43.11.2 Treatment and Prognosis

Exogenous progestins have been used to limited effect. Short-term dexamethasone treatment (5 to 10 mg) may alleviate signs for 3 to 4 days.[44] Bilateral ovariectomy may be successful in some cases.

43.12 RUMINANTS

Common causes of anestrus in cows are summarized in Table 43-3.

43.12.1 UNOBSERVED OR SILENT ESTRUS

43.12.1.1 Cow

Failure of a cow to display, or a manager to observe, the signs of estrus contributes significantly to reproductive inefficiency. When the presenting history suggests anestrus (failure to have a normal estrous cycle), the clinician must determine if the cause is failure of the manager to detect estrus in normal cows or failure of the cow to cycle because of some abnormal process. In dairy herds approximately 90% of cows presented for examination because of a history of anestrus have evidence of normal cyclic ovarian changes,

whereas only approximately 10% are affected by an abnormality that suspends the estrous cycle (i.e., only approximately 10% are in true anestrus).

Nearly 90% of well-managed dairy cows have initiated normal-length estrous cycles by 60 days after calving, but only approximately 60% are detected correctly to be in estrus by that time.[45] Rates of estrous detection by twice-daily observation range from 50% to 73% depending on the skill of the observer.

Table 43-3 Differential Diagnosis of Anestrus in Cows

Cause	Uterus	Ovaries	Peripheral Progesterone	Treatment
Pregnancy	Enlarged; positive signs of pregnancy	Corpus luteum in ovary ipsilateral to pregnant uterine horn	Elevated throughout	Usually none required; PGF or PGF + dexamethasone if unwanted pregnancy
Unobserved estrus	Normal; characteristic tone during estrus; postovulatory edema	Development and regression of corpora lutea and follicular waves diagnosed by sequential examinations	Elevated during diestrus and low for ~3 days before ovulation and ~4 days after ovulation	Improve estrous detection; estrous detection aids; synchronize estrus with PGF; teaser animals
Cystic follicular degeneration	Normal in acute cases; later flaccid mucometra may develop in chronic cases	Fluid-filled cyst(s) greater than 25 mm in diameter; no corpora lutea; unilateral or bilateral; single or multiple cysts	Variable; low in cases of follicular cysts; slight elevation in cases of partially luteinized cysts	Spontaneous recovery; GnRH or hCG to induce luteinization of follicular cysts; PGF for partially luteinized cysts; manual rupture
Pyometra	Variable enlargement; fluid movable from horn to horn, normal-to-thick uterine wall; no positive signs of pregnancy	Corpus luteum in one ovary, frequently contralateral to larger uterine horn	Elevated throughout	PGF
Mummified fetus	Leather-like fetus within involuted uterus; no positive signs of pregnancy	Corpus luteum in ipsilateral ovary	Elevated throughout	PGF; usually slaughter, advisable for economic reasons
Undernutrition	Normal	Small; static; no cyclic changes detected on sequential examinations	Low until corpus luteum forms	Improve quality and quantity of ration
Granulosa-theca cell tumor	Normal	One ovary enlarged; other low atrophic	Low	Surgical removal of neoplastic ovary
Freemartinism	Small to nonexistent	Small to nonexistent	Low	No possible treatment

Ovarian hypoplasia	Very small to near normal	Very small to near normal; unilateral or bilateral; partial or complete	Variable; depends on degree of hypoplasia	No possible treatment

GnRH, Gonadotropin-releasing hormone; *hCG*, human chorionic gonadotropin; *PGF*, prostaglandin $F_{2\alpha}$.

Mounting activity and estrous behavior are reduced by hot and cold ambient temperatures and during the times of milking and feeding. More mounts are observed when cows are kept on dirt than on concrete. Estrous behavior varies with the time of day and may be an inverse reflection of extraneous activity interfering with cow behavior. In one study, 43% of cows showed heat between midnight and 6 AM; 22% between 6 AM and noon; 10% between noon and 6 PM; and 25% between 6 PM and midnight.[46]

Estrus in dairy cows averages 7 to 16 hours in length but ranges from 0.5 to 36 hours. Sixty-five percent of cows are in estrus for less than 16 hours, and 25% are in estrus for less than 8 hours.[47] The number of mounts per hour ranges from 2 to 8, and the total number of mounts during estrus ranges from 11 to 56. Total number of mounts per estrus increases with the number of cows simultaneously in estrus.

43.12.1.2 Clinical Signs and Diagnosis

Dairy herds in which infertility is caused by inaccurate estrous detection are usually characterized by prolonged intervals from calving to first breeding and between services; insemination intervals of 10 to 15 days and 30 to 35 days; records of examinations that confirm cyclic ovarian changes, but in which observation of estrus is not recorded; and finding more than 15% of cows presented for pregnancy examination to be nonpregnant. Insemination during the luteal phase of the estrous cycle may occur in 10% to 20% of cows and is not likely to result in conception; insemination of pregnant cows may be followed by abortion.

The diagnosis of unobserved estrus requires sequential examination of affected cows and accurate records. Other causes of anestrus are eliminated. Conditions such as CFD, pyometra, mummified fetuses, granulosa-theca cell tumors, and segmental aplasia that cause anestrus affect individual animals. Anestrus caused by undernutrition is characterized by depressed milk production and low body condition score.

43.12.1.3 Treatment and Prognosis

PGF is widely used in clinical management of unobserved estrus. Mature CLs (approximately day 6 through day 18 of the estrous cycle) are responsive to PGF-induced luteolysis. Estrus occurs an average of 3 days (range 2 to 5 days) after administration of PGF, depending on the follicular status of the ovaries at the time of injection. The endocrine events surrounding the controlled estrus are indistinguishable from those surrounding spontaneous estrus and ovulation. Treatment with PGF shortens the intervals from treatment to first breeding and from treatment to conception but has no effect on fertility. The benefits of PGF treatment are limited by inaccurate palpation of the temporary ovarian structures, injection during the wrong phase of the cycle, and failure of the manager to observe estrus in treated cows (timed AI can be used to overcome this problem). 1425 1426

Measurement of progesterone concentrations in milk samples taken on the day of breeding is useful in herds with a history of reduced fertility to confirm that cows being inseminated are not in the luteal phase of the estrous cycle. If more than an occasional cow presented for insemination has an elevated concentration of

progesterone, the methods of estrous detection should be reviewed. Enzyme immunoassay kits for measuring concentrations of progesterone in milk and plasma of cows and other female animals have been described and are commercially available.

Various heat detection aids have been developed. Several use devices mounted on the tailhead to record that a cow has stood to be ridden. Pressure-sensitive devices that are glued to the tailhead and change color after sustained pressure by the weight of a mounting cow are commonly used. Similarly, pressure-sensitive devices glued to the tailhead can send a record of riding events directly to a computer. Chalk, cattle crayon marker, or paint applied to the tailhead are inexpensive aids that are rubbed off when the animal is mounted when she is in heat. These methods require daily maintenance and twice daily evaluation to function effectively. Detection aids that measure changes in activity (pedometers), mucous conductivity, or body temperature can be used successfully. Accuracy is enhanced when measurements are related to previous estrous activity and progesterone concentrations.[48]

43.12.1.4 Prevention and Control

Because unobserved estrus is primarily a problem of management, efforts to reduce time lost from delayed breeding are directed at improving efficiency of heat detection. Accurate records are required to identify cows that have not been observed in estrus by 40 days after calving. Cows not observed in estrus by 40 days after calving should be examined, and abnormalities of the reproductive organs that cause anestrus treated as indicated. The time of estrus can be predicted by palpation of the temporary ovarian structures, or estrus can be controlled with PGF. The most significant benefit of a planned herd health program is stimulation of improvements in management that decrease the interval from calving to conception as a result of improved estrous detection.

Anestrus after insemination is frequently interpreted as a clinical sign of pregnancy. However, unobserved estrus in cows that have failed to conceive or have experienced early embryonic death (postservice anestrus) contributes significantly to increased calving intervals. Clinical management of postservice anestrus depends on diligent observation of cows 18 to 24 days after breeding and identification of nonpregnant cows as early as possible after the infertile service so they may be reinseminated with minimum delay. Nonpregnant cows may be accurately identified by ovarian palpation or ultrasonography for absence of a mature CL, by low milk or plasma progesterone at the time of the first expected postservice estrus (approximately 21 days after breeding), or by palpation of the uterus per rectum before the second expected postservice estrus (30 to 42 days after breeding).

43.13 Ewe

The breeding season of most breeds of sheep maintained at temperate latitudes is restricted to late summer, autumn, and early winter, although some breeds cycle all year long. There is almost no homosexual interaction among ewes; therefore a male must be present to stimulate display of estrus.[5]

Introduction of a ram (either intact or vasectomized) into a flock of ewes advances the breeding season. Most ewes ovulate by 3 to 6 days after introduction of rams. The induced ovulation is seldom accompanied by estrus, but the subsequent estrus approximately 17 days later is ovulatory and fertile. The “ram effect” is lost when rams are allowed to associate with ewes throughout the year.

Return to estrus after mating may be detected in a flock of ewes by fitting the ram with a brisket device that marks serviced ewes. Return of an excessive number of ewes to service after breeding alerts the owner to the possibility of infertility.

AI of ewes is rare in the United States but more popular in other countries. Detection of estrus for AI depends on use of teaser rams mingled with the ewes or led through the flock several times daily.

43.14 Doe

The breeding season of does is similar to that of ewes (i.e., it surrounds the autumnal equinox). During periods of short daylight, the normal estrous cycle of does is 20 to 21 days. Homosexual interaction among estrous does rarely occurs; so signs of estrus must be elicited by teasing. Signs of estrus may also be evoked by exposure to male pheromones by way of a “buck jar” prepared by rubbing a cloth over the scent glands caudomedial to the horns of a mature buck during the breeding season and storing the cloth in a tightly closed container. If estrus is not observed in does exposed to a mature buck or to a buck jar during the physiologic breeding season, pregnancy or pseudopregnancy might be considered as possible causes of anestrus. Severely parasitized or inadequately nourished does do not have normal estrous cycles. Deficiencies of phosphorus, iodine, and manganese have been suggested as causes of anestrus in does.

Introduction of bucks into a flock of does early in the breeding season results in initiation of estrous cycles and some degree of synchrony of estrus approximately 10 days after introduction of the bucks.[5] In contrast to ewes, however, the first ovulation after exposure to males is accompanied by estrus and fertile mating.

43.15 Camelids

Most female South American camelids, although showing signs of ovarian cyclicity as early as 5 months of age, have decreased fertility until approximately 15 months of age. A female camelid should be at least 60% of her expected adult weight before she is bred. Male camelids have a preputial attachment of the penis that is not separated until 2 to 3 years of age. Some males may actually detach as early as 15 months of age. Before this time they will show mounting behavior but will not be capable of intromission.[9]

43.16 INFERTILITY CAUSED BY ABNORMALITIES OF THE FEMALE GENITAL ORGANS

43.16.1 ABNORMALITIES CAUSED BY PROBLEMS WITH SEXUAL DIFFERENTIATION

Sexual differentiation occurs in three stages, each stage dependant on the previous one:

1 Chromosomal (genotypic or genetic) sex is determined at fertilization in mammals by the type of sex chromosome contributed by the sperm (X or Y). In mammals, females are XX and males are XY.

1426

1427

2 Gonadal sex is regulated by the *Sry*, (sex-determining region of the Y chromosome) gene, which produces a protein termed the *HY antigen*, as well as other sex-linked and autosomal genes downstream of *Sry*, activation to induce testis formation, or is regulated by the X-linked *Dax1*, to suppress testis formation.

3 Phenotypic sex is regulated by substances produced in the male testes to cause regression of the female tract and formation of the male tract, or, in the absence of a testis, formation of the female tract.

Chromosomal sex is determined at fertilization. All normal mammalian oocytes contribute an X chromosome in addition to one of each representative autosomal maternal chromosome. Sperm cells contribute either an X or a Y sex chromosome in addition to one of each representative autosomal paternal chromosome. Abnormalities in chromosomal sex occur because of nondisjunctional errors during either mitosis or meiosis. Fig. 43-1 shows some examples of chromosomal sex anomalies.

43.16.1.1

Monosomy X (XO)

Monosomy X is also known as *Turner's syndrome*., Owing to the lack of a Y chromosome and the consequent *Sry*, gene, but the presence of the *Dax1*, gene on the present X chromosome, the phenotype is female. Monosomy X is the most commonly reported chromosomal abnormality in mares.[49] Animals with this syndrome often have a history of poor performance and lack of or sporadic reproductive cyclicity. Ovaries are typically inactive, small, smooth, and firm. The uterus and cervix are usually hypoplastic. Externally the mare's genitalia may appear normal or underdeveloped.

43.16.1.2

XXY Syndrome

The genotype for XXY syndrome is part of Klinefelter's syndrome. Because of the presence of a Y chromosome and the consequent *Sry*, gene, affected individuals are phenotypically male; but probably owing to the presence of two copies of the *Dax1*, gene on the two X chromosomes, they generally have hypoplastic genitalia and reproductive organs. It is thought that some factor (*Dax1*, or some other) on the X chromosome must escape the inactivation process, which happens very early in development (around day 7 or 8 in the horse). Testicular development and spermatogenesis are inhibited, resulting in small, flaccid testes and azoospermia. The testes may be retained or descended, but they are often small and soft. The penis may be normal or smaller than usual. Affected males often show normal libido and sexual behavior. Low testosterone concentrations may be noted. Infertility always accompanies this syndrome. Reports have been made in numerous species, including the horse.[50,51]

Fig. 43-1 Examples of chromosomal sex abnormalities.

			Sperm					
			Normal		Abnormal			
			X	Y	XY	XX	YY	O
Eggs	Normal	X	XX	XY	XXY	XXX	XYY	XO
	Abnormal	XX	XXX	XXY	XXXY	XXXX	XXYY	XX
		O	XO	YO	XY	XX	YY	O

43.16.1.3 XXX

More is not better. A report of an infertile mare with the 65,XXX genotype confirms this.[52] The mare had bilaterally small, inactive ovaries, and a hypoplastic uterus and cervix.

43.16.1.4 Mosaics

Mosaics are individuals that have at least two cell lines with different karyotypes arising from the same zygote (Fig. 43-2).

Phenotypes vary in accordance with the degree of mosaicism. Varying degrees of hermaphroditism and pseudohermaphroditism have been reported in many domestic species. Mosaics often have mixed gonadal dysgenesis, with an ovary and a testis, or ovotestes, owing to sex chromosome mosaic cell lines.[53,54] These are true hermaphrodites.

43.16.1.5 Chimeras

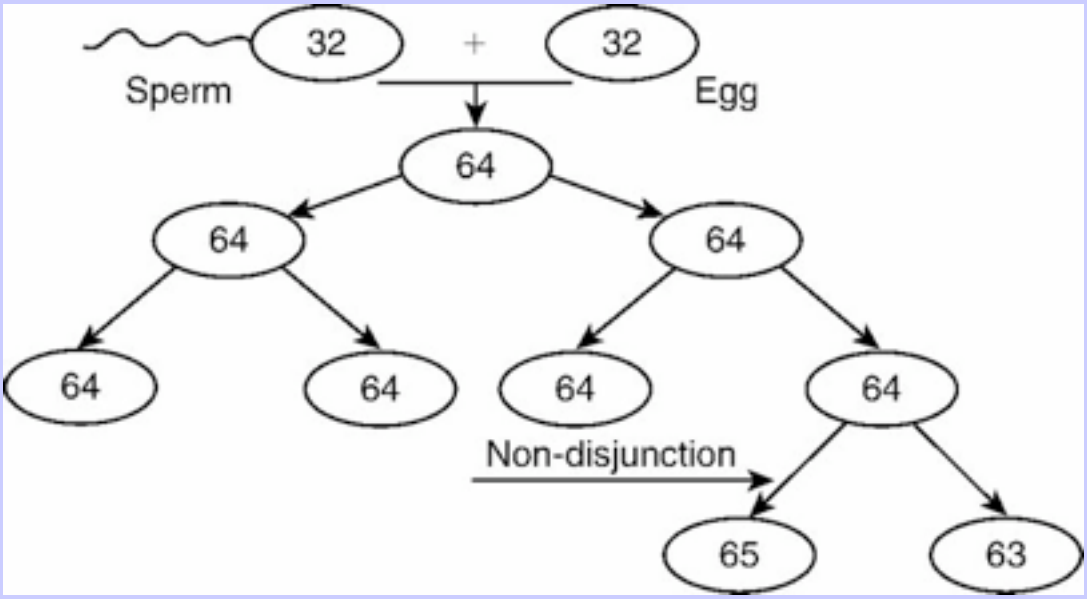
Chimeras are individuals having cell lines from two different embryonic sources. This can occur experimentally or from the natural fusion of blastocysts in utero. The possibility has been reported from a suspected double ovulation and fertilization followed by blastomere fusion in the horse (64,XX/64,XY and 63,XO/64,XY genotypes reported). Freemartinism is a common occurrence in ruminants resulting in chimeric twins.

43.16.1.6 Freemartins

Freemartinism is a phenomenon in ruminants in which an infertile female is twin to a male. The dizygotic occurrence happens when the blastodermic vesicles of the two zygotes fuse early in development (day 18 to 20 in cattle) and share embryonic tissue. The placentas fuse (day 30 to 50 in bovines), and they share blood throughout gestation. This occurs before gonadal differentiation at day 40 to 50. Both individuals are XX/XY chimeras. The *Sry*, gene of the male twin causes the freemartin gonads to develop at least partially toward the male testis. The degree of differentiation varies with each freemartin, and many freemartin gonads remain undifferentiated. The shared circulation allows testosterone and antimüllerian hormone (AMH; discussed later) from the male twin, and possibly from the chimeric freemartin, to affect the freemartin genitalia, and so she lacks a cervix, uterus, uterine tubules, and cranial vagina. The vulva is fairly normal. The yearling freemartin fails to exhibit estrus, the udder and teats remain small, and the freemartin externally resembles a steer (only with a vulva). Diagnosis can be made by establishing a blind end to the vagina (no cranial vagina, no cervix). Of heifers born co-twin to a male, 92% will be freemartins.[55]

1427 1428

Fig. 43-2 Process of how a mosaic may occur. The haploid sperm and egg form a diploid zygote. Through the process of mitosis, diploid cells are replicated to always produce the same number of chromosomes. If, however, a chromosome pair does not separate during anaphase, called a *nondisjunction event*, cell lines that do not reflect a correct representation of the genome will be created and potentially propagated. If this happens with the sex chromosomes in the germ cell line, fertility of the individual or its offspring may be affected.



The male twin may develop into a fertile adult, but these individuals show a higher incidence of infertility than bulls with a 60,XY genotype. Most male twins to freemartins become steers.

Freemartinism is less common in sheep than in cattle, but it does occur. It has also been reported in goats and pigs. With increased fecundity in modern animals, we observe the phenomenon more often than was reported in the past. This is because ovine freemartinism is rare with twins or triplets but much more common with quadruplets or quintuplets. A notable difference between ovine and bovine freemartinism is the marked masculinity of the ovine freemartin. Gonads within the inguinal canal resemble normal prepubertal testes, and those within the abdomen resemble cryptorchid testes from rams of normal XY gonadal sex. Many ovine freemartins also have epididymides, vasa deferentia, vesicular glands, and even cremaster muscles.

43.17 GONADAL SEX

Chromosomal sex determines gonadal sex. The Y chromosome has very few genes, and all of the ones studied play a role in sex differentiation. The gene located at the sex-determining region on the Y chromosome (*Sry*) has a

DNA binding domain high mobility group (HMG) box. It produces a protein called the HY antigen, and its action appears to be regulated by the transcription of other genes. Their actions initiate differentiation of bipotential embryonic gonadal tissue into testicular tissue. Other genes act downstream of *Sry*, to support gonadal differentiation, including *Sox9, Gata4*, and *Wt1*, and *Sf1*, which act synergistically to promote testicular differentiation. *Sox9*, is a powerful promoter of testicular tissue differentiation. It is hypothesized that *Sry*, upregulates *Sox9*, but there is currently no direct evidence to support this. In the absence of the *Sry*, gene, the dual copies of the *Dax1*, gene on the X chromosomes suppress the formation of testicular tissue by antagonizing the *Sry*, gene and the synergy between *Sf1*, and *Wt1*., Another gene, *Wnt4*, has been shown to support female development, and the absence of this gene in female mice results in masculinization.[56] This evidence refutes the notion that female development is strictly a default process caused by the absence of *Sry*., Further research may elucidate other factors that actively promote the formation of ovarian tissue. Factors affecting *Sry*, or any of the other genes downstream of *Sry*, or any factors governing female development will affect phenotypic sex.

43.17.1 Abnormalities of Gonadal Sex: Sex Reversals

Sex reversals occur when the chromosomal sex and gonadal sex do not agree with each other. XX sex-reversed males and XY sex-reversed females are reported in many domestic species. These individuals are either XX males (testicular tissue), XY females (ovarian tissue), or true hermaphrodites (both ovarian and testicular tissue on separate gonads or the same gonad [ovotestes]). Sex reversals are relatively common in the horse, and all three of the types discussed in the following sections are reported. Sex reversal is considered to occur in horses both sporadically and with familial inheritance.

43.17.2 XY Sex-Reversed Females (Gonadal Dysgenesis)

Reported XY sex-reversed females have been reported to arise because of an absent or mutated (and nonfunctional) *Sry*, gene. It is believed that the Sry chromosome is missing because of an abnormal meiotic exchange with the X chromosome. It is thought that in the sire two crossing-over events occurred between X and Y chromosomes during spermatogenesis. These animals are infertile and have a normal female appearance to their external genitalia. The ovaries and uterus tend to be hypoplastic. The gonads may, in fact, be completely undifferentiated (“streak gonads”). These animals may be true hermaphrodites (ovotestes) or XY females (only ovarian tissue).

43.17.3 *Sry*,-positive XX Sex-Reversed Males

Many XX sex-reversed males conversely arise from a translocation of the *Sry*, gene onto the X chromosome. These animals may be true hermaphrodites or XX males (only testicular tissue).

43.17.4 *Sry*,-negative XX Sex-Reversed Males

There are reports in horses of *Sry*,-negative XX sex-reversed males.[57,58] The exact mechanism of masculinization is still uncertain. Possibilities include Y-specific sequences other than *Sry*, (which would require an XY individual with an inactivated or absent *Sry*, gene), XX/XY chimerism within the testicular tissue, and a mutation in an autosomal or X-linked gene farther down the cascade of genes responsible for sex determination. XX sex-reversed males may have ambiguous sexual characteristics and may be true hermaphrodites or XX males (only testicular tissue).

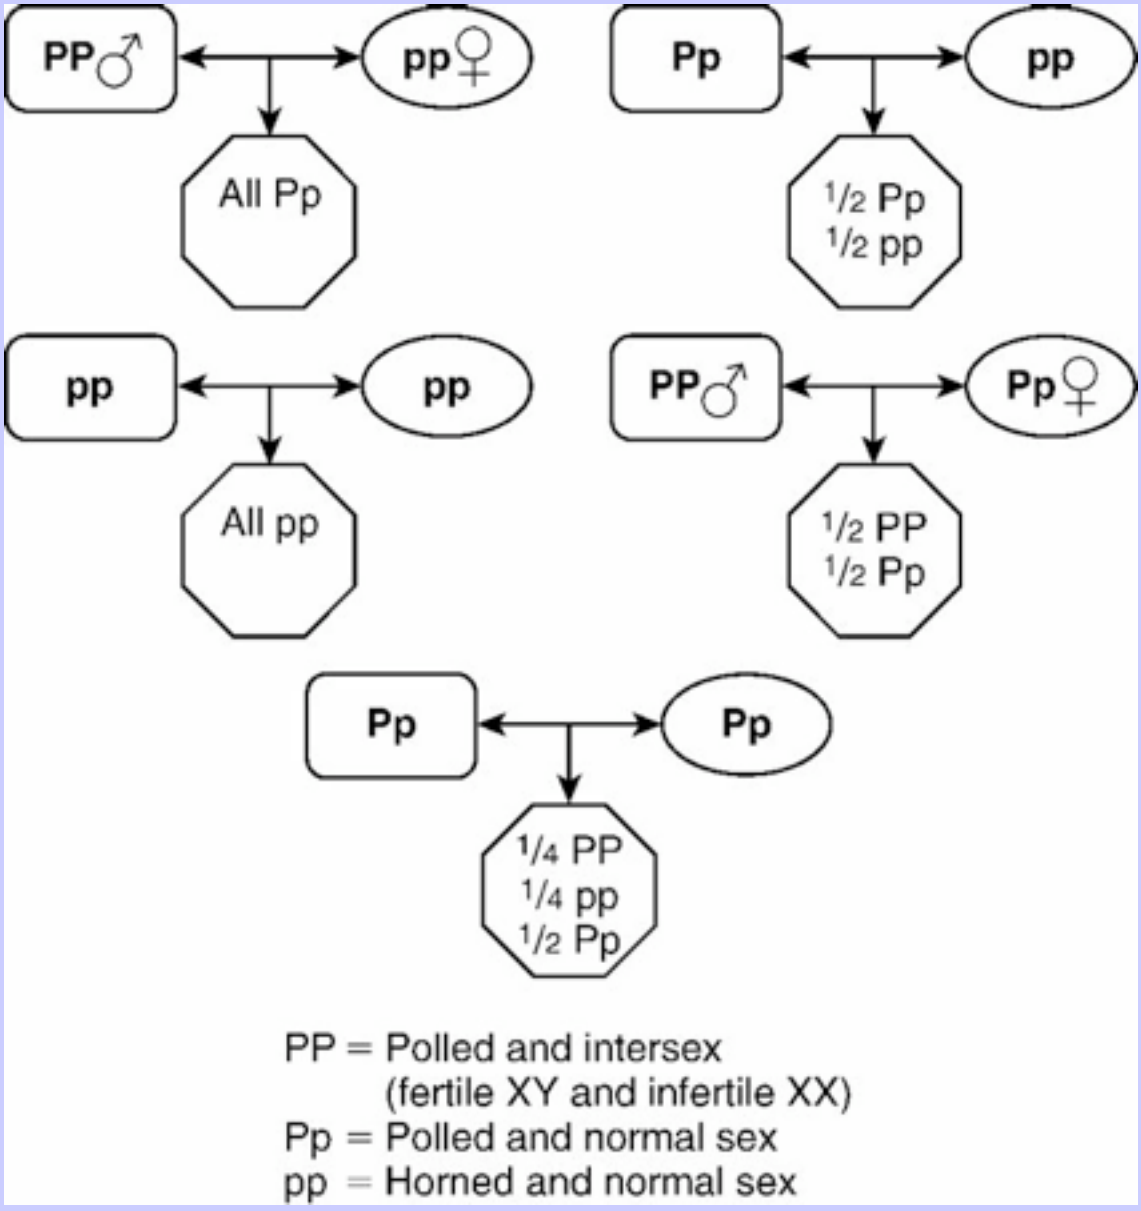
Goats (especially Alpine, Saanen, and Toggenburg) present another classic, common example of *Sry*,-negative XX sex-reversed males. The “polled” (hornless) gene is either very closely linked to an intersex locus, or the polled gene itself is pleomorphic and controls both the hornless and intersex traits. This close linkage or pleomorphism is called the *polled/intersex syndrome*, (PIS). A partial reason for the sex reversal is the deletion that affects a noncoding RNA (Pisrt1) and a transcription factor (FoxL2). The mechanism of testis induction has not been discovered yet. Elucidating this mechanism may be a big step in describing autosomal sex-determining factors in other species, including humans. The intersex gene is currently thought to work by mimicking the *Sry*, gene and codes for the HY antigen.

The polled gene shows a dominant autosomal inheritance pattern, whereas the intersex trait shows a recessive autosomal inheritance pattern. A single dose of the P polled gene is enough to cause the polled trait, but a double dose is required to cause intersexuality in XX individuals. Therefore PP animals are hornless and infertile (if XX, fertile if XY); Pp individuals are hornless (although sometimes have horny bosses) and fertile; and pp individuals are horned and fertile. Intersex individuals are always sterile and have a shortened vagina, large clitoris, bucklike head and neck, buck odor, and buck behavior. The gonads are testes or ovotestes and may be scrotal, inguinal, or abdominal. Even very masculinized intersexes with scrotal testes are azoospermic. A PP polled goat that has an XY genotype is usually initially fertile but often develops sperm granulomas later in life. The only way to avoid the intersex condition is to always breed a polled individual to a horned individual (Fig. 43-3).

43.18 PHENOTYPIC SEX

Gonadal sex determines phenotypic sex. Initially each embryo has both müllerian (paramesonephric) ducts and wolffian (mesonephric) ducts. Within testicular tissue, Sox9 triggers Sertoli cells to secrete müllerian inhibiting substance (MIS; also known as *antimüllerian hormone*, [AMH]), which initiates the irreversible regression of the paramesonephric ducts. The action of MIS or AMH is further regulated by other genes and their proteins (Sf-1, Gata factors, Wt-1, Dax-1, and FSH). Wt-1 and Sf-1 synergistically enhance AMH transcriptional activity. Gata-4 enhances AMH promoter activity by directly binding to DNA and by synergistically interacting with Sf-1. 1428 1429

Fig. 43-3 Assuming classical mendelian genetics, the graph illustrates expected genotypes of progeny from different breedings of polled and wild type goats.



Leydig cells secrete testosterone that is converted by 5α-reductase to dihydrotestosterone. These two steroids promote the differentiation of male genitalia. Testosterone influences the differentiation of the wolffian ducts into the internal male genitalia (vasa deferentia and epididymides), whereas dihydrotestosterone stimulates the formation of the seminal vesicles and male urethra from the urogenital sinus, and the penis from the genital

tubercle. In the absence of these testicular hormones, the wolffian ducts regress and the müllerian ducts become the female internal genitalia.

In the presence of two X chromosomes, the double dose of Dax-1 has an inhibitory effect on the synergistic relationships between Sf-1 and Wt-1 and Gata-4, preventing their support of AMH production.[59] The primitive sex cords (gonadal cords) degenerate in the medulla and remain in the cortex (opposite in the horse). Subsequently there is no communication between the gonad and the mesonephros. In the absence of AMH, the müllerian ducts persist as the oviducts and fuse to form the uterus and cranial vagina. In the absence of testosterone, the wolffian ducts regress. Vestigial traces of these are located in the mesentery of the ovary, the epoophoron, the paroophoron, and Gartner's ducts. The tissues that form the round ligament of the uterus are analogous to the male gubernaculum.

43.18.1 Abnormalities of Phenotypic Sex

Abnormalities of phenotypic sex occur when the chromosomal and gonadal sex agree (XX with ovaries or XY with testes) but the external and/or internal genitalia do not correlate or are ambiguous. Affected animals are the male and female pseudohermaphrodites. The condition can occur because of insensitivity of androgen receptors or because of any abnormality along the pathway that may affect the intervening hormones, such as the conversion of 5α-reductase to dihydrotestosterone.

43.18.1.1 TESTICULAR FEMINIZATION

Testicular feminization is reported in domestic species, including the horse.[60] Patients have external genitalia that are either female or ambiguous in appearance. The vagina may be blind-ending, or the uterus hypoplastic. The gonads are testicles, although they are usually abdominal or inguinal. Male behavior may be reported in horses. The problem lies in the gene for the androgen receptor, located on the X chromosome received from the dam. This X-linked recessive inheritance has been demonstrated in both humans and horses. Affected individuals are male pseudohermaphrodites; the condition has been diagnosed in multiple horse breeds. Serum testosterone is often elevated as a baseline because of loss of negative feedback, or at least in response to an hCG test.

43.19 ABNORMALITIES OF THE OVARIES

43.19.1 MARES

43.19.1.1 ABNORMALLY SMALL OVARIES

The most common causes of bilaterally small ovaries in the mare are (1) seasonal anestrus, (2) immaturity, (3) advanced age, (4) use of anabolic steroids, (5) gonadal dysgenesis, (6) hypothalamopituitary dysfunction, and (7) severe malnutrition. Clinical signs and treatment of malnutrition, hypothalamopituitary dysfunction, and seasonal anestrus are discussed elsewhere in this chapter. The average age at which fillies reach puberty is 18 months, with a wide range of 10 to 24 months. Many older mares (>20 years of age) are still reproductively active, but some mares reach ovarian senescence when they grow older.[61,62] In addition, infertility in aged mares may be a result of defects inherent in ovulated oocytes that result in embryos of lowered viability.[63] Anabolic steroids are derivatives from androgens that have been altered to provide high

anabolic activity with minimal androgenic side effects. A suppression of gonadotropin secretion has been documented when mares have been treated with these drugs.[64] Aberrations of meiosis involving the X and Y chromosomes may lead to genotype abnormalities accompanied by gonadal dysgenesis. Abnormal genotype is most commonly 63X0; but 63X/64XX, 63X/64XY, 65XXX, and 64XY sex reversed have been reported.[65]

43.19.1.1.1 Clinical Signs and Diagnosis

43.19.1.1.1.1 IMMATURITY

Fillies younger than 2 years of age with inactive ovaries and a flaccid and relaxed reproductive tract may be too young to cycle and should be reexamined at a later time. The condition should be differentiated from gonadal dysgenesis. Karyotyping may be indicated if puberty is delayed beyond 24 months.

43.19.1.1.1.2 ADVANCED AGE

Older mares (≥20 years) frequently begin cycling later in the season than younger mares.[61] Older mares that cycle often have a longer follicular phase, and subsequently, a longer interovulatory interval.[61,66] Some aged mares develop large, anovulatory follicles. In one study, significantly more mares aged 16 to 20 years developed anovulatory follicles than mares aged 6 to 10 years.[67] Alternatively, older mares may have fewer follicles on their ovaries and elevated serum gonadotropins. It is postulated that mares with these reproductive characteristics frequently become reproductively senescent.[68] Aged, senescent mares typically have small, inactive ovaries (follicles ≤5 mm) and a flaccid uterus and cervix. Although senescent mares may still show behavioral signs of estrus, similar to anestrous or ovariectomized mares, ovarian function is completely absent.

Oocytes collected from aged donor mares, cultured, and transferred to young recipient mares were less likely to result in pregnancy than oocytes from young donor mares.[63] Furthermore, oocytes obtained from old mares and examined using transmission electron microscopy had more morphologic abnormalities than oocytes from young mares.[69] Results from these studies suggest that oocyte quality declines as mares age, and this factor will contribute to poor fertility in older mares.

1429 1430

43.19.1.2 EXOGENOUS HORMONE TREATMENT

Anabolic steroid administration may affect both estrous behavior and ovarian function. The treatment of mares with low doses of anabolic steroids can cause aggressive or stallion-like behavior, whereas high doses can inhibit ovarian activity and result in failure of follicular development and ovulation.[64] Prolonged treatment of prepubertal mares with anabolic steroids results in hypertrophy of the clitoris.[70]

Progestins are commonly given to cycling mares for the suppression of estrus or synchronization of ovulation. Mares may continue to ovulate during progestin administration, especially if treatment is started late in the luteal phase. A high incidence of persistent CL formation has been observed in mares that ovulate during progestin treatment.[71] Administration of the potent GnRH agonist deslorelin acetate (Ovuplant, Ft. Dodge) to induce ovulation has been associated with delayed follicular development and a prolonged interovulatory interval.[72,73] Deslorelin acetate is very effective in inducing ovulation, but treatment appears

to cause a temporary downregulation of follicle stimulating hormone (FSH) secretion. The low FSH concentrations have been associated with a prolonged period of decreased follicular growth. Administration of $PGF_{2\alpha}$7 to 8 days after ovulation appears to increase the risk of delayed follicular development. It has been suggested that $PGF_{2\alpha}$administration "resets" the timing of the estrous cycle during a period when limited follicular activity is present.

43.19.1.3 GONADAL DYSGENESIS

Chromosomal abnormalities occur in all breeds of horses. Mares are usually small and phenotypically female. The ovaries are small, firm, smooth, and inactive. The tubular tract is thin and flaccid. Endometrial hypoplasia is a common finding. Diagnosis is confirmed by physical findings and karyotype.

43.19.1.4 EQUINE CUSHING'S DISEASE

Mares with hypertrophy, hyperplasia, or adenoma formation in the pars intermedia of the pituitary (equine Cushing's disease [ECD]) have been reported to have abnormal estrous cycles, infertility, or both.[74,75] The mechanisms by which ECD causes reproductive abnormalities have not been determined. Potential cause(s) may be destruction of the gonadotrophs of the anterior pituitary owing to compression by the enlarged pars intermedia[76] or suppression of gonadotropin secretion owing to elevated levels of glucocorticoids or androgens produced by the adrenal cortex.[76] In support of the glucocorticoid hypothesis, administration of dexamethasone to intact mares results in reduced estrous behavior, LH concentrations, follicular growth, and incidence of ovulation.[77] In addition, administration of dexamethasone to ovariectomized mares results in suppression of pituitary LH and FSH secretion,[78] and treatment of pony mares with dexamethasone during the winter eliminates estrous behavior.[79] A majority of horses diagnosed with ECD are older, with the average age being approximately 20 years. Consequently the decrease in reproductive efficiency in mares with ECD may be partly a result of advanced age.

Clinical signs of ECD include hirsutism and abnormal hair-coat shedding patterns, polyuria, polydipsia, and hyperhidrosis.[80] Diagnostic tests for ECD include measurements of serum glucose, insulin, adrenocorticotropic hormone (ACTH) cortisol levels, dexamethasone suppression, ACTH stimulation, and thyrotropin-releasing hormone response tests.[81] The measurement of single samples for basal cortisol or ACTH concentrations is of limited value in the diagnosis of ECD.

43.19.2 Treatment and Prognosis

43.19.2.1 IMMATURITY AND ADVANCED AGE

No treatment is available for age-related ovarian inactivity. Because aged mares often experience a delayed seasonal onset of ovarian activity, they benefit from an artificial light regimen starting 60 to 90 days before the breeding season. GnRH has been used to stimulate follicular growth in mares with poor follicular development attributable to anestrus or transition. Several studies (reviewed by Ginther[23]) have examined the effects of GnRH administered at different doses and intervals to stimulate follicular development in mares. In general, the number of mares responding to GnRH therapy increased as the size of follicle or time of year at the onset of therapy increased.

43.19.2.2 EXOGENOUS HORMONE TREATMENT

Ovarian inactivity in mares treated with anabolic steroids is reversible, and pituitary and ovarian function eventually return to normal in most mares after withdrawal of the treatment. Mares intended for breeding should not be treated with anabolic steroids.

Removal of the deslorelin implant after ovulation has been detected will decrease the incidence of prolonged interovulatory intervals.[82]

43.19.2.3 GONADAL DYSGENESIS

Mares diagnosed with gonadal dysgenesis are sterile, and there is no treatment.

43.19.2.4 EQUINE CUSHING'S DISEASE

The medical management of ECD includes the administration of pergolide mesylate, a dopamine receptor agonist, at a dose of 0.5 to 2 mg every 24 hours in an adult horse. The serotonin antagonist cyproheptadine has also been used, but it may not be as efficacious as pergolide. The dose of cyproheptadine is 0.25 mg/kg every 24 hours, given once in the morning.

43.20 ABNORMALLY ENLARGED OVARIES

The most common causes of enlarged ovaries in the mare are (1) tumors, (2) anovulatory follicles, (3) ovarian hematomas, and (4) pregnancy.

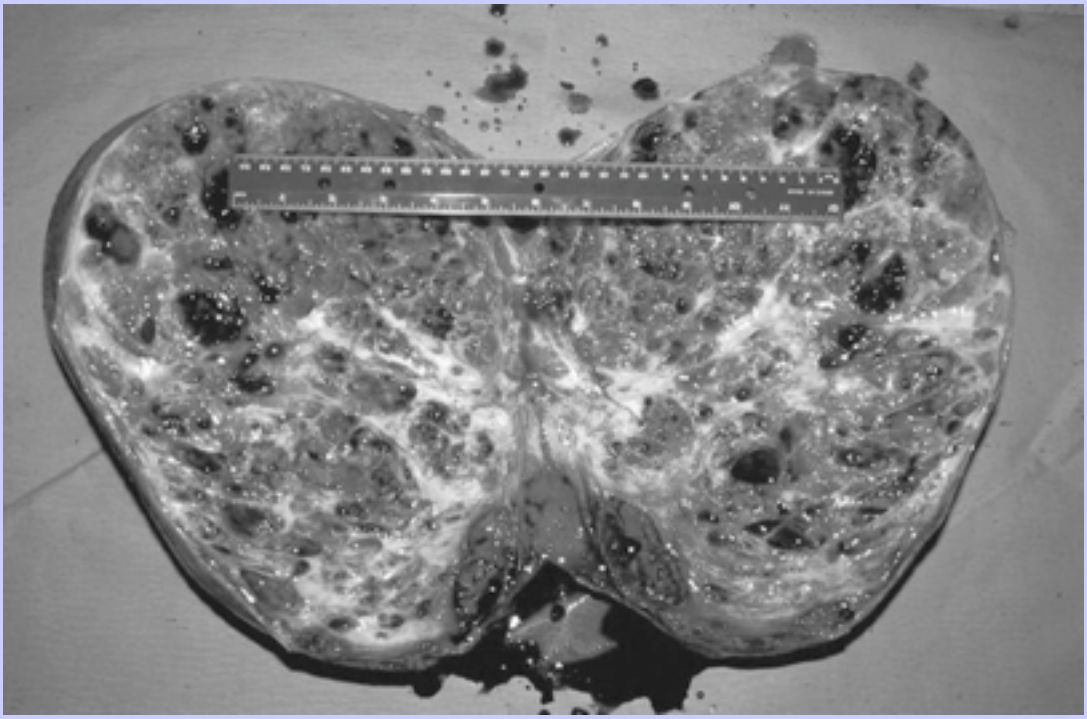
43.20.1 Ovarian Tumors

The majority of equine ovarian tumors can be categorized as sex cord-stromal tumors (granulosa-theca cell tumors), epithelial tumors (cystadenomas), or germ cell tumors (dysgerminomas and teratomas).

43.20.1.1 GRANULOSA-THECA CELL TUMORS

The granulosa-theca cell (GCT) tumor is the most common ovarian tumor in the mare (Fig. 43-4). It is usually slow growing, unilateral, and benign. It occurs in mares of all ages and is occasionally found in pregnant mares. The tumor arises from the steroidogenic cells of the follicle, resulting in abnormal secretion of inhibin and testosterone.

Fig. 43-4 Granulosa cell tumor removed from a mare.



43.20.2 Clinical Signs and Diagnosis

Transrectal sonographic examination of the affected ovary often reveals a multicystic or honeycombed structure, but the tumor may also occur as a solid mass or as a single large cyst. The contralateral ovary is usually small and inactive, although mares with a GCT on one ovary and a functional contralateral ovary have been reported.[83] Granulosa cell tumors are hormonally active, and clinical diagnostic assays for the detection of a GCT include the measurement of inhibin, testosterone, and progesterone.[84–87] α-Inhibin is elevated in approximately 90% of the mares with a GCT.[85,87] It has been hypothesized that inhibin produced by the GCT is responsible for inactivity of the contralateral ovary through the suppression of pituitary FSH release. However, recent reports on a poor correlation between dimeric inhibin and the presence of GCT raise questions about the mechanism by which the contralateral ovary is suppressed in affected mares.[87,88] Serum testosterone in a single blood sample can be expected to be elevated (100 to 200 pg/mL) in approximately 50% to 60% of affected mares. Daily fluctuations in testosterone concentrations have been reported, and repeated samples may have to be obtained on different days in order to detect elevated testosterone.[87] Progesterone concentrations in mares with a GCT are almost always below 1 ng/mL because normal follicular development, ovulation, and CL formation do not occur. As a result of hormone secretion from the tumor, mares may show anestrus, constant estrus, irregular estrus, or stallion-like behavior. They are infertile in the presence of the tumor. Final diagnosis is histologic.

Differential diagnoses for abnormal cyclicity are listed in Table 43-2 and for ovarian enlargement in Table 43-4.

43.20.3 Treatment and Prognosis

The affected ovary should be surgically removed. Surgical approaches for tumor removal include colpotomy, flank and ventral midline laparotomy, and laparoscopy. The prognoses for both life and reproductive use are good. Return to cyclicity varies, but most mares cycle in the year after ovariectomy.

43.21 CYSTADENOMAS

The most common tumor of the surface epithelium of the equine ovary is the cystadenoma. They are rare, benign, hormonally inactive tumors from the surface epithelium of the ovulation fossa. The tumor is unilateral, and the contralateral ovary is normal.

43.21.1 Clinical Signs and Diagnosis

Mares with cystadenomas cycle normally from the opposite ovary and may even become pregnant. Rectal palpation and ultrasonography reveal the presence of one enlarged multicystic ovary, which may appear similar to a granulosa-theca cell tumor, and one normal ovary. Differential diagnoses for ovarian enlargement appear in Table 43-4. Final diagnosis is histologic.

Table 43-4 Unilaterally Large Ovary: Differential Diagnosis

Etiology	Distinguishing Features
Granulosa-theca cell tumor	Sonographically multilocular, high inhibin and/or testosterone; small contralateral ovary
Other ovarian tumor	See text
Ovarian hematoma	Ovulation fossa still palpable, cycles normally
Ovarian abscess	Large, hard ovary; sonographically echogenic
Ovarian follicle	Normal cycling mare, ovulates
Anovulatory hemorrhagic follicle	Free-floating echogenic spots

43.21.2 Treatment and Prognosis

Although cystadenomas are benign tumors and do not affect the reproductive performance of the mare, they are usually surgically removed if diagnosed. The prognoses for both life and reproductive performance are excellent.

43.22 GERM CELL TUMORS

Dysgerminomas and teratomas are rare ovarian tumors of germ cell origin. Both tumors are unilateral and hormonally inactive. Teratomas are considered to be benign, whereas dysgerminomas are potentially malignant.

43.22.1 Clinical Signs and Diagnosis

Both tumors make the affected ovary unilaterally enlarged and multicystic. Dysgerminomas are malignant and often metastasize to the peritoneal and thoracic cavities. Teratomas may arise from all three germinal layers, and the neoplastic ovary may contain bone, cartilage, teeth, hair, muscle, and nerves. Teratomas do not cause clinical signs, interrupt the estrous cycle, or alter the behavior of the mare. Dysgerminomas and teratomas are often detected in association with a routine reproductive examination. Differential diagnoses for ovarian enlargement are listed in Table 43-4. Final diagnosis for germ cell tumors is histologic.

43.22.2 Treatment and Prognosis

Surgical removal is recommended for both dysgerminomas and teratomas. The prognosis for teratomas is usually good, but poor for mares diagnosed with dysgerminomas.

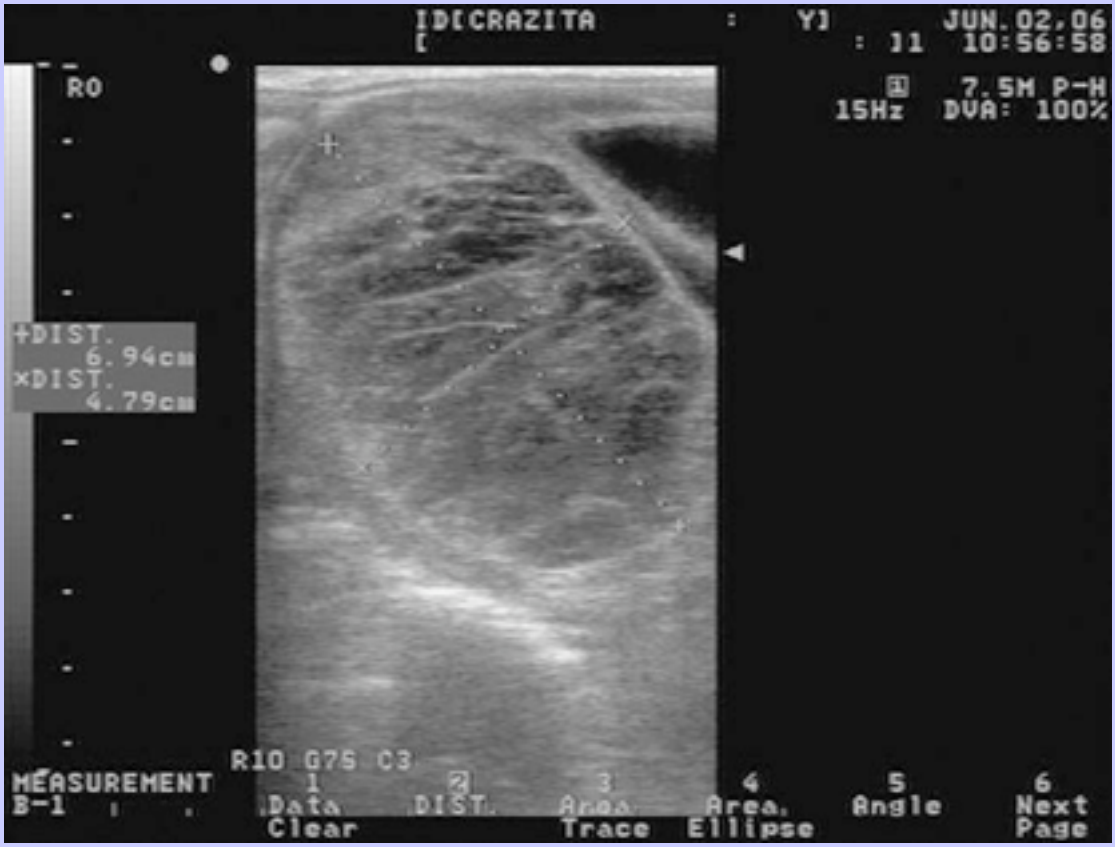
43.23 Anovulatory Follicles

43.23.1 Clinical Signs and Diagnosis

Ovulation failure is a normal physiologic event for the mare during the spring and fall transition periods, but it may also occur occasionally during the physiologic breeding season. Persistent anovulatory follicles (PAFs) may be quite large (5 to 15 cm in diameter), persist for up to 2 months, and result in abnormal estrous behavior and prolonged interovulatory intervals.[89] The cause of ovulation failure has been suggested to be endocrine in nature. Absence of sufficient pituitary gonadotropin stimulation to induce ovulation, or insufficient estrogen production from the follicle, has been proposed as a possible mechanism. PAFs were reported in a recent study to occur in approximately 8.2% of estrous cycles.[67] The formation of an anovulatory follicle was preceded by development of normal endometrial folds or edema in 78.3% of these cases. Initial growth patterns of follicles destined to become anovulatory were usually normal, and the first indication of a problem was the detection of echogenic particles within the follicular fluid. The incidence of PAFs was also found to increase with age.

PAFs may contain blood and have been termed *hemorrhagic anovulatory follicles*., The hemorrhage can be detected ultrasonically as scattered free-floating echogenic spots within the follicular fluid. The follicular fluid may form a gelatinous, hemorrhagic mass within the follicular lumen. Ultrasonographically these structures may contain echogenic fibrous bands traversing the follicular lumen (Fig. 43-5). A thickening of the follicular wall may be observed in anovulatory follicles. This thickening is often associated with luteinization of the follicular wall, and 85.7% of PAFs were found to be luteal structures based on elevations in plasma progesterone concentrations.[67]

Fig. 43-5 Transrectal ultrasonographic image of a persistent anovulatory follicle in a mare.



43.23.2 Treatment and Prognosis

The administration of prostaglandins may result in the destruction of the luteal cells in mares with luteinized PAFs. A majority of nonluteinized PAFs spontaneously regress in 1 to 4 weeks. Treatment with hCG (2500 IU IV) or a GnRH agonist (Ovuplant 2.1 mg subcutaneously [SC]) to induce ovulation or luteinization of the anovulatory follicle is generally not effective. Pregnancy does not usually occur if a persistent follicle eventually spontaneously ovulates or is induced to ovulate. This is likely a result of degeneration of the oocyte over time. Pregnancy obviously will not occur if the follicle becomes hemorrhagic or luteinized without ovulation.

43.24 Ovarian Hematoma

Hemorrhage into the follicular cavity is a normal occurrence at ovulation. Occasionally hemorrhage is severe, resulting in the formation of an ovarian hematoma that may be 10 cm in diameter or larger.

43.24.1 Clinical Signs and Diagnosis

Affected mares continue to cycle normally. Transrectal palpation and ultrasonography reveal an enlarged ovary that is initially irregularly hypoechoic and then echogenic with organization of the hematoma. The ovulation fossa usually remains distinguishable on the affected ovary, and the contralateral ovary remains active.

43.24.2 Treatment and Prognosis

Ovarian hematomas regress spontaneously over a period of weeks or months. The functional lifespan of the luteal tissue in a hematoma is normal, and ovarian activity is unaffected.[90] Because the affected ovary is not permanently damaged and the contralateral ovary is unaffected, the prognosis for fertility is undiminished.

43.24.3 Pregnancy

Multiple secondary CLs form in pregnant mares at 40 to 180 days of gestation, resulting in bilaterally enlarged ovaries that may be mistaken for ovarian pathology.

43.24.3.1 Clinical Signs and Diagnosis

Ovarian enlargement is commonly bilateral. Pregnant mares may show stallion-like behavior associated with increased testosterone production from the fetus during midgestation. Pregnancy should always be considered in a mare with stallion-like behavior, elevated serum testosterone concentrations, and enlarged ovaries. Pregnancy is diagnosed by rectal palpation and ultrasonographic examination.

43.25 PERSISTENT CORPUS LUTEUM

The CL usually regresses 14 to 15 days after ovulation.[3] Although luteal cells appear to be sensitive to $PGF_{2\alpha}$ almost immediately after ovulation, complete luteolysis and return to estrus in response to endogenous or exogenous $PGF_{2\alpha}$ will not occur until 5 days after ovulation. Because the functional CL is lysed by $PGF_{2\alpha}$ from the endometrium, the CL will continue to function in the following situations.

1. In the pregnant mare the equine conceptus produces a PGF inhibitor factor, which is secreted as early as day 11 to 13 after ovulation.[23] The factor prevents PGF from being synthesized and secreted from the endometrium. This results in a prolonged luteal phase of the primary CL until the development of endometrial cups and secretion of eCG ensure the presence of functional luteal tissue in the pregnant mare.
2. Embryonic loss after the time of maternal recognition of pregnancy can result in a persistent CL for a variable period of 35 to 90 days.[91]
3. Destruction of the endometrium in infectious and inflammatory conditions such as pyometra may cause insufficient synthesis of PGF and prolonged luteal life.[92]
4. Late diestrous ovulation will result in a CL that is insufficiently mature to respond to endogenous PGF release.[1]

5 Nonsteroidal antiinflammatory drugs may inhibit endometrial PGF synthesis, resulting in a prolonged luteal phase.

6 Spontaneous CL persistence has been proposed as a clinical entity[76] but has not been adequately documented and is an area of controversy.[93]

43.25.1 Clinical Signs and Diagnosis

This syndrome may be suspected clinically in mares that are not expressing normal estrous behavior during the physiologic breeding season, and it must be differentiated from mares with silent heat. Diagnosis of a persistent CL is made by transrectal sonographic examination of the ovaries. The CL appears as a well-defined hyperechoic structure on the ovary. Mares with a persistent CL will have good cervical and uterine tone on palpation, and the cervix will appear tight and dry on vaginal speculum examination because of the influence of progesterone. The diagnosis may be confirmed by analysis of plasma progesterone concentrations or a clinical response to prostaglandin administration. Progesterone concentrations >1 ng/mL[1] are indicative of the presence of active luteal tissue. Differential diagnoses are listed in Table 43-2.

43.25.2 Treatment and Prognosis

After pregnancy has been ruled out with sonographic examination, luteolysis can be achieved with administration of 10 mg of the PGF product dinoprost tromethamine or similar PGF analog. The mare must be at least 5 days postovulation to respond reliably to treatment. If the mare is treated with PGF in the presence of a mature diestrous follicle (≥35 mm), she may ovulate the follicle without signs of estrus in response to declining progesterone concentrations that allow LH to be secreted from the anterior pituitary. An ultrasonographic or rectal examination of ovarian follicular activity should therefore always be performed before PGF is administered to induce estrus.

43.26 SHORTENED LUTEAL PHASE (PREMATURE LUTEOLYSIS)

Premature (<15 days) luteolysis is associated with an early onset of estrus and a decrease in the interovulatory interval. The most common cause of premature luteolysis in the mare is endometritis. Inflammation of the endometrium results in an acute activation of inflammatory mediators. One of these mediators is $PGF_{2\alpha}$, which in addition to its inflammatory effect also may cause luteolysis and return to estrus. Consequently a mare that exhibits a shortened diestrus should be examined for endometritis. A culture, biopsy, and cytologic examination of the uterus may be indicated.

43.27 LUTEAL INSUFFICIENCY

Primary luteal insufficiency implies a deficiency in progesterone production. Luteal insufficiency has been suggested to be a cause of subfertility in mares.[94] Maintenance of pregnancy in some habitually aborting mares after administration of exogenous progestogens offers circumstantial evidence that progesterone insufficiency may be responsible for some cases of pregnancy loss.

Data are limited and not supported by scientific evidence from controlled studies.

Luteal insufficiency secondary to $PGF_{2\alpha}$ release in mares with endotoxemia has been reported[95] and should be considered in pregnant mares with gram-negative infection and/or endotoxemia-associated colic. Reports on the effect of exogenous administration of $PGF_{2\alpha}$ during the periovulatory period suggest that $PGF_{2\alpha}$ can delay the formation of a functional CL. Suboptimal concentrations of progesterone were found in mares after treatment with $PGF_{2\alpha}$ during the first 2 days after ovulation.[96–100] Although the CL eventually became functional and progesterone concentrations had returned to normal levels at day 14, pregnancy rates were significantly lower in treated mares.[97,98]

43.27.1 Clinical Signs and Diagnosis

The minimum concentration of progesterone required to maintain pregnancy in the mare has been suggested to be 2 ng/mL.[95] Repeated samples are necessary to diagnose luteal insufficiency because progesterone is released episodically.

43.27.2 Treatment and Prognosis

The most common treatment for luteal insufficiency is supplementation with the synthetic progestogen altrenogest (Regumate) at a dose of 0.044 mg/kg PO once daily. Options for duration of altrenogest supplementation include treatment until day 80 to 120 of pregnancy or greater and measurement of endogenous progesterone level of >2 ng/mL (progesterone and altrenogest do not cross-react on radio immunoassay [RIA]), or treatment until the end of gestation. It is important to emphasize the need to monitor fetal well-being when mares are kept on progestin supplementation to maintain pregnancy. A case of fetal mummification of a 5-month-old fetus in a pregnant mare at term has been reported.[101] The mare had been maintained on altrenogest throughout gestation.

43.28 RUMINANTS

43.28.1 PROLONGED LUTEAL FUNCTION

43.28.1.1 Cow

Spontaneous prolongation of luteal function in the presence of a normal, nongravid uterus does not occur in cows. But several conditions affecting the uterus do suspend the luteolytic mechanism, resulting in prolonged luteal function, persistently elevated progesterone concentrations, and anestrus. Common causes of prolonged luteal function in cows include pregnancy, pyometra, mummified fetus, and segmental aplasia, including uterus unicornis.

43.28.1.1.1 Clinical Signs and Diagnosis

Pregnancy resulting from an unobserved or unrecorded breeding must always be considered as a possible cause of anestrus. Examination of the uterus by transrectal palpation or ultrasonography for one of the positive signs of pregnancy (fetal membrane slip, amnionic vesicle, placentomes, or fetus) must precede administration of PGF.

Pyometra is characterized by accumulation of variable amounts of mucopurulent exudate within the uterine lumen, failure of luteolysis, and subsequent anestrus. An enlarged uterus as a result of fluid accumulation and a thickened uterine wall in the absence of any positive signs of pregnancy can be used to differentiate uterine enlargement caused by pregnancy from that caused by pyometra. Fluid associated with pyometra is more viscous than fetal fluid and can be manipulated from horn to horn. Because the cervix is nearly always closed, there is generally no vaginal discharge.

Fetal mummification is occasionally encountered in dairy and beef cows and is characterized by fetal death, failure of expulsion, absorption of fetal fluids, and persistence of the CL. Cows with fetal mummification are usually presented when they do not deliver a calf at the expected time. The condition can be differentiated from pregnancy by palpation per rectum of a dried, leather-like fetus within the involuted uterus. Fetal membranes cannot be slipped, and fetal fluids and placentomes are absent.

43.28.1.1.2

Clinical Pathology

No remarkable changes in hematology and clinical chemistry are associated with pregnancy, mummified fetus, or pyometra in cows. In all three conditions, peripheral concentrations of progesterone remain elevated above 1 ng/mL of plasma until spontaneous luteolysis occurs or the condition is treated.

43.28.1.1.3

Treatment and Prognosis

Unwanted pregnancy is seldom encountered in dairy cows, but when cows or heifers are mated by accident or to an undesired sire, abortion may be reliably induced with PGF products (25 mg of dinoprost tromethamine,* or 500 mcg of cloprostenol;† two injections 8 to 12 hours apart) after 7 days and before 150 days of gestation or with a combination of PGF and dexamethasone (20 mg) beyond 150 days of gestation. The PGF products are also the treatment of choice for pyometra in cows. Mummified fetuses are usually expelled 3 to 5 days after treatment with PGF. The mummy may pass through the cervix, but the vagina is likely to be dry and may not dilate sufficiently, so the mummified fetus may be retained. If the mummified fetus is not expelled by 5 days after treatment, a vaginal examination should be performed, and the mummy delivered by gentle traction if necessary. The prognosis for fertility after delivery of a mummified fetus is good.

† Estrumate, Mobay Corporation, Animal Health Division, Shawnee, KS.

43.28.2

OVARIAN HYPOPLASIA

Ovarian hypoplasia occurs sporadically as an autosomal recessive trait in the cow. The condition has incomplete penetrance; therefore it may be partial or complete and unilateral or bilateral. The affected gonad varies in size from a cordlike thickening in the cranial edge of the mesovarium to a bean-sized structure. The tubular genital organs remain infantile in animals with complete bilateral hypoplasia or may develop to near-normal size in heifers with unilateral or partial hypoplasia. Individuals affected with complete bilateral ovarian hypoplasia are sterile, whereas those affected by partial or unilateral hypoplasia may be subfertile. With partial hypoplasia the uterine pole of the ovary is typically affected. On direct observation by laparotomy or laparoscopy or on slaughter, the uterine pole is flat and triangular and shows converging striations. The affected part is devoid of follicles. Animals with partial ovarian hypoplasia can be expected to have a reduced

superovulatory response to gonadotropin treatment. Heifers with abnormal karyotypes are also affected by ovarian hypoplasia. The condition should be differentiated from nonfunctional ovaries and anestrus associated with malnutrition or debilitating diseases. Treatment of ovarian hypoplasia is not successful.[102]

43.28.3 FREEMARTINISM

43.28.3.1 Cow

A freemartin is a phenotypic female, born co-twin to a male, that is sterile because of arrested development of the reproductive tract. The term “freemartin” is said to have originated in England, where it referred to a heifer that was not pregnant after the summer breeding season and therefore “free” for fattening and slaughter at Martinmas, a fall festival in honor of St. Martin.[11] Freemartinism arises as a result of anastomoses between the placental circulations of twin fetuses of opposite sexes. Sexual differentiation of the male embryo occurs earlier than that of the female; therefore the male twin may sterilize the female by transfer of HY antigen, which inhibits development of the female gonad. The ovaries of a freemartin are underdeveloped and contain seminiferous tubules. Abnormalities of the tubular genital organs vary in severity, and the structures range from cordlike bands to near-normal uterine horns. In most freemartins there is no cervix; therefore no communication exists between the uterus and vagina. The latter is a short blind pouch. Frequently, seminal vesicular glands of varying size are present.

As many as 92% of phenotypic females born co-twins to males are freemartins[55]; the history suggests a diagnosis in most cases. Singleton freemartins are possible if male and female twins are conceived and the male is lost after 30 days of gestation. Palpation per rectum of breeding age freemartins reveals aplasia or hypoplasia of the tubular genital organs and hypoplastic ovaries. If animals too small for palpation per rectum are presented, examination of the vagina with a small glass speculum (or test tube) reveals that the vagina of a freemartin is short (6 to 7 cm in freemartins versus nearly double that length in normal heifers). A definitive diagnosis may be made by karyotyping the suspected individual; varying percentages of male cells are found in freemartins.[102] More details on freemartinism are discussed elsewhere in this chapter.

43.28.3.2 Ewe

Although freemartinism is possible in sheep, the condition is rare, despite the high incidence of multiple births. The condition can be confirmed by determination of blood cell chimerism.

43.28.3.3 Doe

Twinning is also common in goats, but vascular anastomosis is either uncommon or occurs after the critical period for sexual differentiation. Caprine freemartins comprise approximately 6% of intersexes.[5]

43.28.4 INTERSEX

43.28.4.1 Doe

Intersexes are common among Saanen, Toggenburg, and Alpine goats. The fetal testes appear to be unable to fully masculinize the duct system or external genitalia. Parts of both the mesonephric and paramesonephric

ducts persist; therefore the phenotype of affected individuals may approach that of either sex. Intersexes are most frequent among polled goats, and the condition is thought to be caused by a recessive gene linked to that for polledness; however, intersexuality may rarely be seen in horned goats. Diagnosis is based on a history of abnormal sexual behavior, and identification of abnormal genital development is by physical examination. There is no satisfactory treatment, but the prevalence of the condition may be reduced by preventing mating between two polled animals.[5] More detailed information can be found elsewhere in this chapter.

43.28.5 OVARIAN TUMORS

43.28.5.1 Granulosa Cell Tumor

43.28.5.1.1 COW

Although rare, various ovarian neoplasms have been described in cows; granulosa cell tumors appear to be most common.[11]

43.28.5.1.1.1 Clinical Signs and Diagnosis

Granulosa-theca cell tumors are characterized by unilateral ovarian enlargement, with the affected ovary being greater than 10 cm in diameter. The surface may be smooth or coarsely lobulated. Function of the contralateral ovary may be suppressed. The behavior of affected cows ranges from anestrus to nymphomania to bull-like behavior. Udder development and lactation may occur in affected heifers. Very few bovine granulosa cell tumors are malignant, and they rarely metastasize. Among the other ovarian neoplasms that have been reported in cattle are dysgerminomas, interstitial cell tumors,[11] and teratomas. Causes of ovarian enlargement that must be differentiated from ovarian neoplasia include ovarian cysts, oophoritis, ovarian abscesses, and parovarian cysts.

43.28.5.1.1.2 Treatment and Prognosis

The treatment for ovarian neoplasia in cattle is surgical removal of the affected ovary; however, cows may not be as fertile as mares after removal of the tumor.

43.28.5.1.2 EWE

Granulosa-theca cell tumors have been reported, but tumors of the genital organs of ewes appear to be rare.[11] Animals with ovarian tumors may exhibit all types of behavioral and physiologic abnormalities (nymphomania, inappropriate lactation). Diagnosis is based on ultrasonographic evaluation of ovaries per rectum or transabdominally. Treatment is ovariectomy.

43.28.5.1.3 DOE

Ovarian neoplasia appears to be rare in does as well. Granulosa-theca cell tumors and dysgerminomas have been reported.

43.28.6 OVARIAN HEMORRHAGE

43.28.6.1 Cow

Ovulation tags develop after ovulation, resulting from blood loss associated with rupture of the follicle.[11] Fine adhesions may develop between the ovarian surface and surrounding structures. Most ovulation tags resolve spontaneously and have no effect on fertility. Severe ovarian hemorrhage may follow attempts to manually enucleate the CL. Adhesions between the ovary and its bursa interfere with their normal function. Enucleation of CLs for treatment of anestrus and pyometra has been superseded by treatment with PGF products.

43.28.7 OOPHORITIS

43.28.7.1 Cow

Inflammation of the ovary may follow traumatic manipulations, such as enucleation of CLs and attempts to drain fluid from ovarian cysts, and ascending infections from the uterus. Oophoritis may also accompany brucellosis, mycoplasmosis, and tuberculosis.

43.29 INFERTILITY CAUSED BY ABNORMALITIES OF THE FEMALE TUBULAR GENITALIA

43.29.1 SALPINGITIS

Inflammation of the oviducts is characterized by macroscopic enlargement. Lesions are frequently bilateral and consist of infiltration by lymphocytes, plasma cells, and neutrophils, and desquamation of epithelial cells.[11]

Most cases of salpingitis follow infections of the uterus. Necrotizing and granulomatous salpingitis may follow infection by *Arcanobacterium pyogenes, Mycobacterium tuberculosis*, and *Brucella abortus*., Mild inflammation of the uterine tubes that does not usually result in permanent damage accompanies uterine infection caused by *Campylobacter fetus*, subsp. *venerealis*, and *Tritrichomonas foetus*., Salpingitis may be a sequela to manipulations of the ovaries and uterine tubes by palpation per rectum, transvaginal ovum pickup, aggressive irrigation of an infected uterus, and inappropriate treatment with estrogenic hormones. Migrating larvae of *Strongylus edentatus*, have been proposed as a possible cause of nonobstructive infundibulitis in mares, but their role is speculative.[11]

Pyosalpinx is characterized by segmental accumulation of pus within the lumen of the oviduct after mechanical blockage of either end. Pyosalpinx frequently follows severe cases of uterine infection and may be complicated by perimetritis and localized peritonitis.

Hydrosalpinx is characterized by accumulation of thin mucus within the lumen of the oviduct. Hydrosalpinx and adhesions to perisalpingial tissues are common sequelae to chronic salpingitis.

43.29.1.1

Clinical Signs and Diagnosis

The usual history associated with diseases of the uterine tubes is one of infertility. Additional history may include uterine infection or traumatic therapy such as uterine irrigation, enucleation of CLs, or administration of exogenous estrogen during CL function. Salpingitis is an uncommon clinical finding in the mare. However in one study, up to 88% of mares were found to have macroscopic lesions in the oviduct, including adhesions, fibrous bands, and parovarian cysts, which may or may not have affected fertility.[103] Accumulations of cells and debris may form intraluminal masses; however, their role in infertility has not been adequately tested.[104] The pathology of the oviduct has been reviewed.[105] Similarly, moderate lesions of uterine tube disease may escape diagnosis by physical examination in cows, but the results of abattoir studies suggest that lesions of the oviducts are not uncommon.[11] In cows, lesions involving adhesions among the ovary, ovarian bursa, oviduct, and surrounding tissues may be identified per rectum by inserting two or three fingers into the ovarian bursa and rolling the oviduct between the fingers and thumb. Easy identification of the oviduct by palpation per rectum is sometimes considered indicative of abnormalities. Diagnosis of diseases of the oviducts in ewes and does is impossible by physical examination. Although a history of infertility after one of the predisposing causes might suggest oviductal lesions, diagnosis is made by exploratory laparotomy, peritoneoscopy, or necropsy.

Lesions of the oviductal or perisalpingial tissues must be differentiated from other causes of abnormal enlargements such as ovarian neoplasia, parovarian cysts, cystic ovarian disease, and ovarian hematomas. Neoplasia of the oviducts in domestic animals is extremely rare.

43.29.1.2

Clinical Pathology

Several tests that determine oviductal patency of mares[106] and cows[107] have been described, but neither the starch test nor the phenolsulfonphthalein dye test is very reliable or consistently diagnostic. For suspected unilateral blockage,[108] each uterine horn may be catheterized individually with a Foley catheter placed at the base of the horn on different days.

43.29.1.3

Embryo Recovery

Embryo recovery after either a single ovulation or superovulation is objective evidence that one or both uterine tubes are patent and functional. Improved reproductive performance of cows may follow uterine lavage; therefore embryo recovery as a diagnostic test may have therapeutic benefits as well.[109]

43.29.1.4

Treatment and Prognosis

Treatment of diseases of the oviducts is not likely to be successful. Appropriate treatment for concurrent uterine infections should be instituted. A period of sexual rest may be beneficial and is indicated in valuable animals. The prognosis for reproduction in cases of bilateral obstruction of the oviducts is poor. In vitro fertilization of ova harvested from affected females is a therapeutic option. Affected females can also serve as embryo recipients.

43.29.1.5 Prevention and Control

Traumatic manipulation of the ovaries, irrigation of the endometrial cavity with large volumes of fluid (over 100 mL in heifers or 150 mL in cows) or irritating chemicals, and administration of estrogenic hormones to luteal phase females should be avoided.[102] Because abnormalities of the oviducts are frequently associated with uterine infections, reduction of the prevalence of uterine infections results in fewer tubal infections as well.

43.29.2 UTERINE ABNORMALITIES

43.29.2.1 Retained Fetal Membranes

43.29.2.1.1 MARES

Retention of the fetal membranes beyond a period of 3 hours is an abnormal occurrence in the mare. The mare has an epitheliochorial placenta characterized by diffuse microvilli that interdigitate with endometrial crypts. After delivery, blood flow through the placental vessels is reduced, and placental microvilli shrink and disengage from endometrial crypts. The condition is more common after abortion, dystocia, cesarean section, and fetotomy. The pathophysiology of the disease is poorly understood but may involve disturbances of normal prepartum endocrine events or myometrial contractility. Partial placental retention may be localized to well-defined areas of continued placental attachment. The most common site of partial retention is the previously nongravid horn.

Equine placentas should be spread on a flat surface after expulsion and examined to ensure that the complete membrane is present. Areas of placental necrosis are common near the tips of the uterine horns, and the fragile area may be incarcerated by the rapidly contracting uterus.

43.29.2.1.1.1 Clinical Signs and Diagnosis

Retained fetal membranes (RFMs) are usually visible at the vulva. However, small tags of placental tissue may remain attached to the uterus without being apparent and may be a nidus for infection, resulting in severe metritis, endotoxemia, and laminitis hours to days postpartum.

43.29.2.1.1.2 Treatment and Prognosis

The severity of sequelae makes early intervention essential. Treatment should begin if fetal membranes are not passed within 3 hours of foaling. Most instances respond to vigorous early pharmacologic treatment. Occasional cases require several days of persistent treatment.

43.29.2.1.1.2.1 MANUAL REMOVAL

Manual removal is contraindicated because trauma induces placental tearing, leaving microvilli in endometrial crypts.

43.29.2.1.1.2.2

OXYTOCIN

Oxytocin induces myometrial contractions, which may aid placental expulsion. Oxytocin may be administered by intravenous injection (5 to 20 IU every 15 to 30 minutes) or intramuscular injection (20 to 40 IU every 30 to 60 minutes), or it may be infused slowly (30 to 80 IU in 500 mL of warm saline over 30 to 60 minutes). Care should be taken to avoid overdosage, which may result in signs of abdominal pain and which will cause tetanic rather than orchestrated uterine contraction.

43.29.2.1.1.2.3

ALLANTOCHORIONIC INFUSION

If the chorioallantois is intact, the chorioallantoic cavity may be filled to distention with 3 to 4 gallons of warm saline or water through the cervical star.[111] The opening in the placenta is held closed until the mare exerts abdominal pressure. Oxytocin may be used in conjunction with this treatment.

43.29.2.1.1.2.4

UTERINE LAVAGE

If the chorioallantois is not intact, uterine lavage with an isotonic saline solution will clear debris, encourage myometrial contractions, and may help to free the retained fragment of the fetal membrane. The isotonic saline solution may be infused into the uterus through an equine nasogastric tube (dedicated to reproductive use) manually held in place. Approximately 5 L may be placed in the uterus of a full-grown, postpartum mare at one time, but care should be taken to observe the mare for signs of discomfort and to gauge the amount of fluid felt within the uterus. During fluid infusion the operator may carefully explore the uterus manually, searching for retained fetal membrane remnants. Once the uterus is relatively full of fluid, the fluid is siphoned out. Care must be taken to protect the fragile endometrium from damage incurred by the strong suction force of the siphon. The operator's hand should guard the end of the tube from direct contact with the endometrium. This process should be repeated until the effluent is clear. Uterine lavage should be performed at least once daily until 12 to 24 hours after the RFM remnants are retrieved.

43.29.2.1.1.2.5

ADJUNCT THERAPY

Concurrent therapy directed at controlling or minimizing common sequelae to retained placenta is often indicated.

1 *Antibacterials*., Bacterial infections are commonly associated with prolonged (>6 to 8 hours) retention of the fetal membranes. The bacterial population is frequently mixed and likely to include beta-hemolytic streptococci and coliforms. In prolonged cases bacterial culture and sensitivity should be performed. Broad-spectrum antibiotics known to be effective against commonly isolated organisms are indicated. Drugs that have been recommended for systemic administration include ampicillin, gentamicin, kanamycin, penicillin, ticarcillin (with gentamicin for *Pseudomonas*, infection), and trimethoprim-sulfamethoxazole. Intrauterine administration of antibiotics and antiseptics depresses phagocytic activity of uterine neutrophils, and many chemicals irritate the endometrium, but drugs that have been suggested include those recommended for systemic administration, as well as amikacin and polymyxin B.

2 *Antiinflammatory drugs*., Laminitis may be a sequela to metritis and is commonly associated with RFMs. Treatment with administration of antiinflammatory drugs such as phenylbutazone or flunixin meglumine is indicated to reduce the likelihood and severity of laminitis. Polymyxin B may also be indicated in cases in which preliminary signs of laminitis are noted, because of its antiinflammatory and antiendotoxic effects. Additional therapy for laminitis should be administered as indicated.

3 *Other treatments*., Caslick's surgery may be indicated in some cases of RFMs to control aspiration of air. Tetanus may complicate RFMs, and prophylaxis with tetanus antitoxin in unvaccinated animals or tetanus toxoid in previously vaccinated animals is indicated.

Some cases of RFMs are refractory to treatment, and membranes may remain firmly attached to the endometrium for several days. Aggressive attempts at manual removal should be eschewed, because severe endometrial damage may follow. Persistent treatment with antibiotics, antiinflammatory drugs, and oxytocin is indicated until the placenta is expelled and bacterial infection of the uterus is controlled.

The prognosis for RFMs is generally good but is reduced if treatment is delayed or if retention is accompanied by infection with virulent pathogens. Sequelae to RFMs include metritis, endometrial fibrosis, invagination of a uterine horn, uterine prolapse, and laminitis.

43.29.2.1.2

RUMINANTS

43.29.2.1.2.1

Cow

The cotyledonary placenta of cows is usually expelled within 3 to 8 hours after calving and is considered retained if not expelled by 12 hours. RFMs are more commonly seen in dairy than in beef breeds. In dairy cattle the reported prevalence ranges from 8% to 12% after spontaneous delivery of single calves. RFMs are more likely after deliveries of male calves or twins and deliveries complicated by dystocia. Parturition after a shorter- or longer-than-normal gestation length is accompanied by an increase in the incidence of RFMs.[112]

1436
1437

The cause of RFMs in cattle is failure of fetal cotyledons to separate from crypts of maternal caruncles; the process of separation normally begins during the last months of pregnancy. Villi shrink after blood flow is interrupted by rupture of the umbilical vessels. Strong myometrial contractions continue during the third stage of labor, and changes in the size and shape of maternal caruncles contribute to separation of the placenta from the endometrium. A number of factors have been associated with separation failure, but the precise reasons for separation failure are unknown.[5] Deficiencies of selenium, vitamin E, and vitamin A are associated with an increased prevalence of RFMs.[5]

43.29.2.1.2.2

Clinical Signs and Diagnosis

The majority of affected cows show no serious clinical signs other than a transient decrease in appetite and milk production. However, 20% to 25% of cows affected by RFMs develop moderate to severe metritis. The most objectionable clinical signs are the malodorous discharge and objectionable tissue hanging from the genital tract. RFMs are usually expelled by 4 to 10 days after calving when the

caruncular tissue has become necrotic and is sloughed. Some affected cows show signs of endotoxemia, including depression, fever, ruminal stasis, and inappetence, as a result of RFMs.

43.29.2.1.2.3

Treatment and Prognosis

A variety of treatments have been suggested for RFMs in cows, including aggressive attempts at manual removal, myometrial stimulants, intrauterine and systemic antibiotics (alone or in combination with other approaches), and no therapy whatsoever. Because the processes that culminate in RFMs begin during late gestation, it is not unreasonable that treatment initiated at calving has little effect on the loosening process. Most treatments for RFMs are directed toward controlling the intrauterine bacterial population.

43.29.2.1.2.3.1

MANUAL REMOVAL

Manual removal of the placenta is indicated only when gentle traction is sufficient to withdraw the membranes in a short time. Attempts at manual removal are contraindicated if the patient shows clinical signs of septicemia. Trauma caused by manual removal inhibits phagocytosis by uterine neutrophils and predisposes to severe sequelae, including septic metritis and peritonitis.

43.29.2.1.2.3.2

MYOMETRIAL STIMULANTS

Administration of a single dose of oxytocin does not reduce the prevalence of RFMs in cows that calve spontaneously or in cows that require assistance at delivery.[113,114] Cows with RFMs have an elevated plasma concentration of estrogen during the period of retention; therefore administration of additional estrogen for treatment of RFMs may be of questionable value.[115] Intravenous calcium solutions are indicated in cases of RFMs secondary to hypocalcemia.

43.29.2.1.2.3.3

PROSTAGLANDIN

In one trial, treatment with fenprostalene resulted in a shorter period of retention in treated cows, reduced the number of treatments subsequently required for metritis, and slightly reduced the intervals to first service and conception.[116] However, other researchers found that fenprostalene produced no changes in myometrial activity between days 1 and 4 after calving and concluded that uterotonic agents are unlikely to hasten placental expulsion because uterine effort is already increased in animals that have RFMs.[117] An imbalance between synthesis of PGF_2 and PGI_2 between 30 and 60 minutes after parturition has been demonstrated in cows affected by RFMs.[118] Prostaglandin at the time of calving does not reduce the incidence of RFMs or improve reproductive performance.[119]

43.29.2.1.2.3.4

ANTIBIOTICS

Intrauterine tetracycline may reduce fertility,[120] or the reproductive performance of treated cows may be as good as that of untreated herdmates.[7] Intrauterine treatment with 4 to 6 g of oxytetracycline per day until the placenta is expelled may reduce the prevalence of metritis associated with RFMs, but pyometra may develop in treated cows.[121] Bacterial putrefaction and the disagreeable odor of RFMs

may be reduced by intrauterine antibiotics, but the placenta is released only after necrosis of the caruncles. Systemic and intrauterine antibiotics are indicated in cases of RFMs in which the cow has a fever, is off feed, or has a drop in milk production.

Cows that retain their membranes for more than 12 hours after calving are more likely to develop metritis than are cows that promptly expel the membranes. However, reproductive performance of cows that rapidly return to normal after RFMs is similar to that of their unaffected herdmates, indicating that in the absence of a secondary reproductive abnormality, RFMs have a minimum effect on future fertility.

43.29.2.1.2.3.5

COLLAGENASE

An alternative approach to the treatment of RFMs is the injection of collagenase into the umbilical arteries of the retained membranes.[122] This treatment is aimed directly at the lack of cotyledonary proteolysis. Intrauterine infusion of collagenase is not effective. Bacterial collagenase from *Clostridium histolyticum*, is used and is commercially available (Type XI, Sigma Chemical, St. Louis, Mo.). However, collagenase is not currently approved for use in food-producing animals in the United States.

43.29.2.1.3

Ewe and Doe

Fetal membranes are considered retained in ewes and does if not expelled within 12 hours after delivery of the last fetus. The prevalence in does is approximately 6% after spontaneous delivery but may be higher when delivery is complicated by dystocia or abortion. Selenium deficiency has been suggested as a cause.

The clinical signs of RFMs in ewes and does are usually obvious.[5] Does may ingest their placentas, complicating identification of cases of partial retention. RFMs may accompany retention of a fetus within the uterus, and does and ewes should be carefully examined.

Other tissues that may be exposed from the vulva in association with parturition are a prolapsed uterus, a prolapsed or everted urinary bladder, prolapse of some portion of the digestive tract through a uterine rupture, prolapsed rectum, prolapsed vagina, or a twin fetus.

43.29.2.1.4

Treatment and Prognosis

Manual separation of cotyledons from caruncles is impossible in ewes and does; therefore manipulative attempts to remove the placenta are limited to gentle traction on exposed membranes at daily intervals. Treatments with intrauterine and systemic antibiotics, oxytocin (10 to 20 IU) at 12-hour intervals until the placenta is expelled, and antiinflammatory drugs have been suggested. Prophylaxis against tetanus is indicated.

43.29.2.2

Camelids

The placenta is usually passed within 1 to 2 hours of parturition. Camelid placentas resemble equine placentas (diffuse, microcotyledonary, epitheliochorial), with the exception that the left horn is almost always the pregnant horn. RFMs in camelids are most commonly seen as sequelae to dystocia or other disorders of parturition.[9] Treatment is similar to that described for the mare.

43.30 UTERINE INFECTIONS

43.30.1 MARE

43.30.1.1 Endometritis

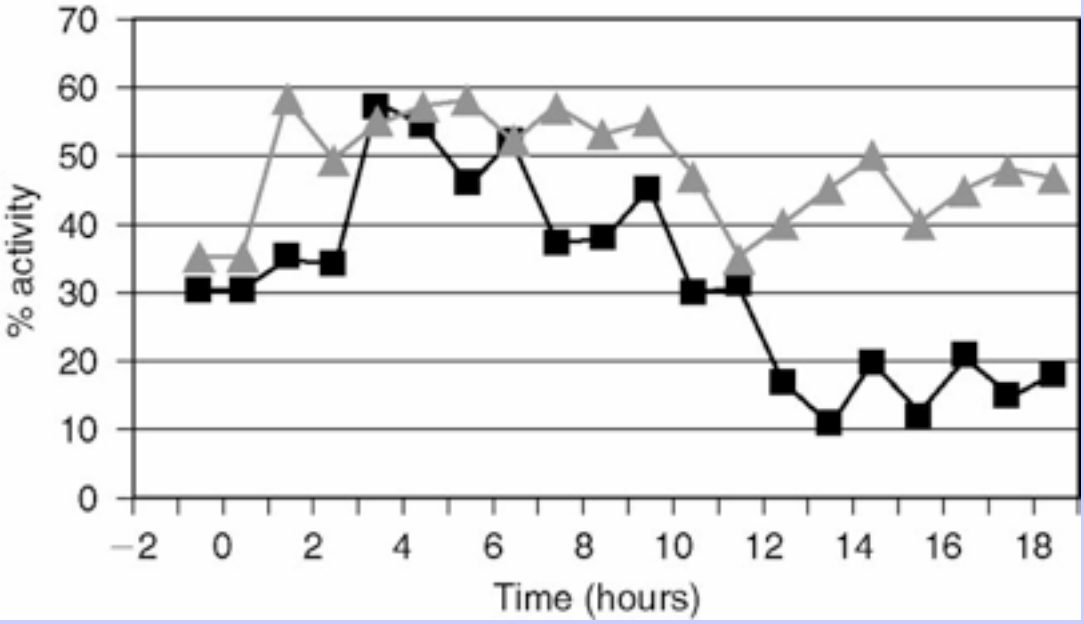
A failure of the uterine defense mechanisms to effectively eliminate an antigen (bacteria or spermatozoa) and inflammatory products from the uterus results in persistent endometritis, which is a major cause of reduced fertility in broodmares.[123] In the normal mare the uterus is well protected from external contamination by physical barriers consisting of the vulva, the vestibule, the vagina, and the cervix, and any compromise of these barriers may predispose the mare to a chronic uterine infection.[124] Breeding is another source of uterine contamination. Intrauterine deposition of semen causes an inflammatory reaction resulting from bacterial contamination of the ejaculate or from spermatozoa.[125] Approximately 15% of a normal population of thoroughbred broodmares developed persistent endometritis after breeding.[126] Natural resistance to experimentally induced bacterial contamination has been demonstrated in young mares, whereas a population of multiparous and barren mares developed persistent endometritis after bacterial contamination of the uterus.[127,128] Based on these studies, mares have been classified as either susceptible or resistant to persistent uterine infection.[127] Endometritis has severe effects on the fertility of affected mares. A persistent inflammation may interfere directly with the survival of an embryo or may cause premature luteolysis and embryonic loss because of increased PGF concentrations.[129]

Several classes of immunoglobulins have been isolated from the equine uterus. Although antibody-mediated uterine defense may be important for effective elimination of bacterial contaminants from the uterus in susceptible mares, concentrations of immunoglobulins in uterine secretion are similar or even elevated compared with those of resistant mares.[130–134] Polymorphonuclear neutrophils (PMNs) are the first inflammatory cells to enter an inflamed site.[135] Chemoattractive properties of uterine fluid have been described in vitro in horses, and the uterus responds quickly to an antigen with release of PMN-chemotactic mediators, which results in a rapid migration of PMNs into the uterine lumen.[136] Complement products and leukotriene B_4 (LTB_4), PGE, and PGF may all serve as chemoattractants for PMNs in the uterus.[136–140] Studies on the role of local uterine factors in PMN function suggested that an impaired phagocytosis by uterine PMNs in susceptible mares is the result of insufficient opsonization in uterine secretion rather than a primary dysfunction of the PMNs.[141]

Mechanical aspects of the uterine defense system are currently believed to be a major contributor in uterine clearance of bacteria and inflammatory products.[142–144] Through use of intrauterine inoculations of a combination of radioactive-labeled microspheres and bacteria, impaired uterine clearance was demonstrated in susceptible but not in resistant mares.[142] Studies using scintigraphic measurements of intrauterine clearance of radioactive colloids further defined a delayed physical clearance in susceptible mares.[143] Through use of electromyography (EMG) to register myometrial activity, it was observed that the impaired uterine clearance in susceptible mares was caused by reduced myometrial activity in response to the inflammation (Fig. 43-6).[144] The dependent position of the mare's uterus may also interfere with effective clearance.

Based on pathogenesis, persistent endometritis can be divided into (1) sexually transmitted diseases (STDs), (2) persistent uterine infection, (3) persistent breeding-induced endometritis, and (4) chronic degenerative endometritis (endometrosis).

Fig. 43-6 Myoelectrical activity before and after uterine inoculation of *Streptococcus zooepidemicus*, in mares susceptible (▪) and resistant (▲) to persistent endometritis. Time 0 indicate time of inoculation. Susceptible mares had impaired myoelectrical activity after inoculation. Modified from Troedsson MH, Liu IK, Ing M, et al: Multiple site electromyography recordings of uterine activity following an intrauterine bacterial challenge in mares susceptible and resistant to chronic uterine infection, *J Reprod Fertil*, 99:307, 1993.



43.30.1.2

SEXUALLY TRANSMITTED DISEASES

Few true STDs are known in the horse. Contagious equine metritis (CEM) is an example of a true STD.[145,146] The disease is caused by *Taylorella equigenitalis*, a highly contagious and pathogenic microorganism. Although the present status of a mare's uterine defense mechanism is important for the manifestation of the disease, this bacterium is highly resistant and capable of overcoming the mare's normal disease barriers.

43.30.1.3 PERSISTENT UTERINE INFECTION

Bacteria most commonly isolated from the uterus of the mare are beta-hemolytic streptococci (*Streptococcus zooepidemicus*, and *Streptococcus equisimilis*), *Escherichia coli, Pseudomonas aeruginosa*, and *Klebsiella pneumoniae*., Other aerobic bacteria isolated from reproductive tracts of mares include alpha-hemolytic streptococci, *Corynebacterium*, species, *Staphylococcus*, species, *Enterobacter*, species, *Actinobacter*, species, *Proteus*, species. *Citrobacter*, species, *Candida*, species, and *Aspergillus*, species are the organisms most commonly associated with yeast or fungal endometritis. The role of viruses, mycoplasmas, ureaplasma, and anaerobic bacteria in endometritis is poorly understood. *P. aeruginosa, K. pneumoniae*, and possibly *S. zooepidemicus*, and *E. coli*, can be sexually transmitted in horses, but the consequences of exposure to these microorganisms are determined by the particular strain involved and active participation of all facets of the mare's uterine defense mechanisms. In contrast to a true STD, persistent infectious endometritis is often the result of contamination of the uterus by the mare's fecal and genital flora in combination with compromised uterine defense.[147,148]

43.30.1.4 PERSISTENT BREEDING-INDUCED ENDOMETRITIS

43.30.1.4.1 Bluegrass

Intrauterine deposition of semen causes an inflammatory reaction resulting from spermatozoa.[149,150] The mechanism of the induced inflammation is similar to endometritis caused by bacteria, involving activation of the complement cascade.[150] The role of spermatozoa in breeding-induced endometritis implies that a transient uterine inflammation is a physiologic reaction to semen, and it appears to be a normal process by which excess sperm and bacterial contamination are eliminated from the mare's reproductive tract.[148,151] Transport of spermatozoa from the uterus to the oviduct is completed within 4 hours after breeding, and only a small portion of the ejaculated or inseminated semen reaches the oviduct.[152,153] The rapid transport of spermatozoa to the oviduct coincides with increased uterine activity.[151] Increased myometrial contraction in response to breeding is also responsible for rapid sperm elimination from the uterus through the cervix.[154] However, not all excess spermatozoa are removed from the uterus through this mechanism. The remaining spermatozoa have to be eliminated by means of other uterine clearance mechanisms, such as PMN-phagocytosis of spermatozoa.[148] However, the condition may develop into a persistent inflammation in mares with impaired uterine clearance.[142,143] If sperm elimination and all physical and chemical reactions that are involved in the induced inflammation persist beyond the time when the embryo enters the uterus at 5 days after ovulation, embryonic loss will occur because of an incompatible inflammatory uterine environment. The incidence of persistent breeding-induced endometritis has been reported to be approximately 15% of a normal population of thoroughbred broodmares, and the incidence may be higher for mares bred by artifical insemination with thawed frozen semen.[126]

1438

1439

In contrast to spermatozoa, seminal plasma has a suppressive effect on complement activation, PMN-chemotaxis, and phagocytosis.[155] A function of seminal plasma may be to act as an inflammatory inhibitor or modulator in the uterus, which may be of importance with regard to the transient nature of breeding-induced endometritis. The duration of breeding-induced uterine inflammation was shown in a study to be shorter when seminal plasma was included in an insemination dose, compared with when all seminal

plasma was removed and replaced by a commercial semen extender.[156] Although the peak numbers of PMNs were the same for both groups, significantly fewer PMNs were recovered from the uterus at 24 hours compared with 6 and 12 hours after insemination when seminal plasma was included. In contrast, there was no significant difference in the number of uterine PMNs at 6, 12, and 24 hours of insemination in the absence of seminal plasma. Another function of seminal plasma in breeding-induced endometritis may be to protect spermatozoa from being phagocytosed and destroyed in an inflammatory environment. PMNs are present in the uterine lumen by 0.5 hours after breeding, but sperm transport is not completed until 3 to 4 hours later.[152,157] In addition, when mares are inseminated twice within a 24-hour period, semen from the second insemination is introduced into an inflammatory environment. This environment is detrimental to sperm motion characteristics, and motile sperm cells appear to bind to PMNs, forming large clusters of PMN and spermatozoa. Addition of seminal plasma has been shown to reduce the binding between spermatozoa and inflammatory cells in vitro.[158] Recent data suggest that equine seminal plasma selectively protects viable but not dead spermatozoa from PMN-binding and phagocytosis.[159,160] Selective protection of viable spermatozoa from PMN-binding and phagocytosis increases their survival in a hostile uterine environment and ensures that a sufficient number of spermatozoa reach the oviduct for fertilization, while effective sperm elimination of nonviable spermatozoa can be maintained.

43.30.1.5

CHRONIC DEGENERATIVE ENDOMETRITIS (ENDOMETRIOSIS)

Degenerative changes of the endometrium such as periglandular fibrosis and glandular dilation are often seen in older multiparous mares. The condition is associated with susceptibility to persistent endometritis[161] and may result from repeated uterine inflammation. However, the condition has also been observed in older mares without any known history of endometritis, suggesting that degenerative fibrosis of the endometrium can be a process of aging rather than inflammation.[162] Based on the possibility of a noninfectious cause of the disease, it was suggested that the condition should be called *endometrosis*, rather than *degenerative endometritis*.,[162] It is not clear why mares with fibrotic degenerative changes to the endometrium have an impaired physical uterine clearance mechanism. Sclerotic changes in the uterine vascular bed impair blood flow to both the endometrium and the myometrium.[163]

43.30.1.5.1

Diagnostic Approach

History compatible with endometritis includes infertility after breeding to a fertile stallion. Mares with severe endometritis may have shortened interestrous intervals and may show vaginal discharge. Physical and speculum examination may show anatomic defects of the vulva or cervix. Excessively easy passage of a vaginal speculum may indicate loss of integrity of the vestibulovaginal sphincter. Discharge from the cervix and vaginal inflammation may be apparent. Transrectal palpation and ultrasonography may reveal accumulations of luminal fluid (Fig. 43-7). Diagnostically, it may be difficult to identify susceptibility to breeding-induced endometritis before breeding. Some mares have free fluid present in the uterine lumen before breeding, but most mares are not diagnosed until after they have been bred. If susceptibility to persistent breeding-induced endometritis is suspected, the mare should be monitored closely by ultrasonography per rectum at 6 to 12 hours after breeding, if possible, and at a minimum within 24 hours after breeding. If free fluid is present in the uterine lumen, the mare should be considered to have persistent mating-induced endometritis. Clearance of charcoal particles from the uterus within 48 hours of inoculation and the use of scintigraphy to measure uterine clearance have been suggested to be useful in

identification of mares that are susceptible to persistent breeding-induced endometritis.[143,164] However, these methods may not be practical under field conditions.

43.30.1.6

MICROBIOLOGY

Quantitative aerobic bacterial culture of the uterine lumen is necessary to identify potential pathogens and for antibiotic sensitivity testing. Samples should be taken during estrus, and the swab plated immediately on a solid medium or transported in a nonnutritive medium to the laboratory. Inadvertent contamination of cultures with bacteria from the lower reproductive tract is common, so the culture instrument should be guarded until it is within the uterus.[165] A false-positive bacterial sample result may be obtained as the result of contamination (even when double-guarded swabs are used), and culture results should always be interpreted together with results from endometrial cytology. Culture alone is not diagnostic. False-negative swab sample results are frequently obtained even under optimal circumstances, and laboratory results should always be interpreted in light of clinical findings. Use of culture and histologic interpretation of an endometrial biopsy appears to be the most accurate method to diagnose persistent infectious endometritis.[166] Cultures may also be performed on endometrial biopsy samples. Culture samples for *T. equigenitalis*, should be taken from the endometrium, cervix, clitoral fossa, and sinuses. Samples should be placed in Amies medium with charcoal or Steward's medium and be kept refrigerated until delivered to the laboratory.

Fig. 43-7 Transrectal ultrasonographic image of uterine intraluminal fluid accumulation in a mare with endometritis.

Table 43-5 Endometrial Biopsy Grade and Fertility Prognosis (Kenney and Doig)

Biopsy Category	Degree of Change	Predicted Foaling Rate (%)
I	None	80–90
IIA	Mild	50–80
IB	Moderate	10–50
III	Severe	<10

43.30.1.7

ENDOMETRIAL CYTOLOGY

PMNs migrate into the uterine lumen in response to inflammation, so endometritis is rapidly and accurately diagnosed by examination of exfoliated endometrial cells. A sample may be taken with a guarded swab, a cytology brush, or by infusion and aspiration of a small amount of fluid. Air-dried smears are stained with new methylene blue or modified Wright-Giemsa stain. Epithelial cells may be shed singly or in rafts. Arbitrary definitions of endometritis have been established on the basis of relative numbers of PMNs. Using these criteria, more than one PMN per 10 epithelial cells is consistent with endometritis. Endometrial cytology from normal mares may contain PMNs and spermatozoa for several days after breeding. It has been suggested that eosinophils are associated with fungal endometritis and pneumovagina. Urine crystals indicate urovagina.

43.30.1.8

ENDOMETRIAL BIOPSY

Endometrial biopsy is an accurate diagnostic and prognostic tool for endometritis. The biopsy sample should be taken during the breeding season, should be of adequate size, and should be fixed in Bouin's solution for 24 hours and then transferred to 10% formalin. Chronic endometritis is characterized by infiltration of the endometrium with mononuclear cells and deposition of layers of fibrosis around endometrial glands. Fibrosis of the endometrium is a degenerative change and is permanent. The severity of endometrial changes is inversely related to reproductive performance. A system to classify histologic changes has been described and is widely used[5] (Table 43-5). Special stains such as periodic acid—Schiff and Gomori's methenamine silver may be used to identify the presence of fungi in endometrial biopsies.

43.30.1.9

TRANSRECTAL ULTRASONOGRAPHY

The presence of free intraluminal fluid before breeding strongly suggests susceptibility to persistent endometritis.[167] Ultrasonographic examination of the uterus is helpful to assess both the quantity and quality of accumulated fluid in the uterine lumen. Normal mares may retain fluid up to 6 to 12 hours after mating. If fluid is present at 12 hours or more after breeding, the mare should be considered to have a persistent mating-induced endometritis.[168] Increased echogenicity of the fluid is associated with the presence of inflammatory cells and debris.

43.30.1.9.1

Hysteroscopy

Examination of the uterine lumen with an endoscope provides information about degree of inflammation in addition to evidence of foreign bodies, transluminal adhesions, intraluminal masses, and endometrial cysts.

43.30.1.10

Treatment and Prognosis

43.30.1.10.1

SEXUALLY TRANSMITTED DISEASES

Mares with CEM should be treated with intrauterine infusions of antibiotics based on sensitivity tests, in combination with local treatments of the clitoral fossa and sinuses. Best results can be expected when treatment is initiated when the mare is in estrus and is combined with uterine lavage if inflammatory debris or intraluminal fluid is present. Cleansing of the vulva and the clitoris daily for 5 days with a 4% chlorhexidine or nitrofurazone ointment has been recommended.[169] Sinusectomy can also be performed.[170] Import regulations in countries free from CEM serve to prevent outbreaks of the disease. The spread of CEM on farms in endemic countries is best prevented by implementation of strict hygiene, screening of breeding stallions before the breeding season, and the use of AI, if allowed by the breed registry.

43.30.1.10.2

PERSISTENT UTERINE INFECTION

Treatment of mares with persistent uterine infections needs to be directed toward the underlying breakdown of the uterine defense and against the microbial agent. The first therapeutic concern should be to remove predisposing causes, such as a breakdown of external genital barriers. Persistent uterine infection frequently follows degenerative or traumatic anatomic changes and loss of integrity of the barriers of ascending infection. Therefore Caslick's surgery, repair of cervical damage and perineal lacerations, and correction of urovagina should precede specific endometrial treatment. All potential sources of contamination including intrauterine passage of diagnostic and treatment implements should be minimized. In some mares, recovery follows with sexual rest and no further treatment. Mares that are susceptible to persistent uterine infections should be bred using minimal contamination techniques to avoid bacterial contamination of the uterus.[171] Antibiotics may be administered by either local or systemic routes. Intraluminal fluid and inflammatory debris should be removed by uterine lavage before local treatment. Drugs and doses are summarized in Table 43-6. Treatment should be based on sensitivity. Mares should be treated during estrus when natural defense is maximal, and strict aseptic technique should be used. The volume of fluid used for antibiotic therapy is dependent on the size of the uterus. A total volume of 30 to 60 mL is usually sufficient. Treatment should continue daily for 4 to 6 days during the duration of estrus. Bacterial resistance may follow inadequate dosage, and follow-up cultures should be performed. Repeated contamination may indicate an unsuccessfully resolved predisposing cause. Removal of the primary microorganism may result in overgrowth of a second bacteria or fungus (superinfection). Critical studies of the efficacy of systemic antibiotics are limited, although effective levels are produced in the endometrium after systemic administration.[172] Parenteral administration may be easier, and the opportunity to introduce uterine contamination or cause uterine irritation with treatment is eliminated. Treatment of fungal infections is generally more challenging than treatment of bacterial infections. Culture and sensitivity will determine the choice of antifungal drugs (Table 43-6). Fungal endometritis may require daily intrauterine infusions for 7 to 10 days to effectively resolve the infection. In order to avoid

intrauterine infusions in the presence of high circulating concentrations of progesterone, treatment can be initiated 1 or 2 days after an injection of $PGF_{2\alpha}$ in diestrual mares and continues until 1 or 2 days after ovulation. A single dose of a benzyoylphenyl urea (lufenuron) has recently been suggested to effectively treat mares with fungal endometritis.[173] Initial data from four mares were encouraging and need to be confirmed by controlled studies using larger groups of mares.

Treatment with immunostimulatory agents *(Propionibacterium acnes)*, has been reported to improve pregnancy rates in mares with persistent endometritis, but the mechanism is not fully understood.[174]

1440

1441

Table 43-6 Antibacterial Drugs Used for Intrauterine Administration for Treatment of Uterine Infections in Mares

Drug	Dose (Intrauterine Administration)	Comments
Amikacin sulfate	2 g	Gram-negative spectrum; buffer with equal volume of 7.5% bicarbonate
Ampicillin	3 g	Gram-negative spectrum; may irritate the endometrium
Carbenicillin	2–6 g	Gram-negative spectrum; may irritate the endometrium; buffer with equal volume of 7.5% bicarbonate
Gentamicin sulfate	1–3 g	Gram-negative spectrum; buffer with equal volume of 7.5% bicarbonate
Kanamycin sulfate	1–3 g	*Escherichia coli*, spermatocidal
Neomycin sulfate	3–4 g	Useful against sensitive *E. coli*,
Potassium penicillin G	5 million U	*Streptococcus zooepidemicus*,
Polymyxin B	1 million U	*Pseudomonas*,
Ticarcillin	6 g	Broad spectrum
Ticarcillin/clavulanic acid	6 g/200 mg	Broad spectrum
Ceftiofur	1 g	Broad spectrum *(S. zooepidemicus)*,
Antimycotics		
Nystatin	500,000 U	Dissolve in 30 mL 0.9% saline solution; daily for 7 to 10 days
Clotrimazole	500 mg	Suspension or cream; daily for 1 wk
Miconazole	500 mg	Effective against yeast
Amphotericin B	200–250 mg	Daily for 1 wk
Vinegar	2%	20 mL wine vinegar to 1 L 0.9% saline solution; used as uterine lavage
Lufenuron	540 mg (single dose)	Suspend in 60 mL sterile water

43.30.1.10.3

PERSISTENT BREEDING-INDUCED ENDOMETRITIS

Management of mares susceptible to persistent breeding-induced endometritis should include limiting uterine exposure to semen and bacteria and assisting the uterus to physically clear contaminants and inflammatory products after breeding.[136,173,175] Preexisting uterine infections should be resolved before the mare is bred. Exposure to semen should be limited to a single breeding per cycle, if possible. This can be accomplished by closely monitoring follicular development and hormonal treatment to induce ovulation of mature follicles. Physical clearance can be assisted by the use of uterotonic drugs. Oxytocin or $PGF_{2\alpha}$ treatment 4 to 8 hours after breeding has been shown to aid in uterine clearance, resulting in improved pregnancy rates in susceptible mares.[136,167,173,176] Care must be taken with regard to the timing of $PGF_{2\alpha}$ treatment. Recent reports have demonstrated that $PGF_{2\alpha}$ can cause a delay in the formation of a functional CL when administered within 2 days after ovulation.[96–100] This was associated with pregnancy failure in two of the reports.[97,98] Large-volume uterine lavage 6 to 24 hours after breeding will also effectively assist the uterus in clearing fluid and inflammatory products.[175] Because sperm transport to the oviduct is completed within 4 hours after breeding, uterine lavage 6 to 24 hours after breeding will not have a negative effect on fertility.[152] Manual dilation of the cervix in mares with poor cervical dilation may help these mares to more effectively clear the uterus of fluid.

The use of corticosteroids in mares with excessive inflammation in response to breeding has been suggested.[177] The authors administered acetate 9α-prednisolone (0.1 mg/kg) twice daily during estrus, starting when a follicle >35 mm was detected and ending when ovulation was confirmed. Preliminary results are encouraging, and further research is needed to clarify the mechanism of action for this treatment alternative.

Electroacupuncture has been used clinically to increase uterine contractility in mares with delayed uterine clearance. Anecdotal reports are encouraging, and research is needed to confirm the efficacy of this treatment alternative.

It is important for the clinician to keep in mind that a transient inflammatory response to semen is normal and required for normal fertility. Postbreeding treatments of these mares will most likely not improve fertility but may cause even further contamination and interfere with pregnancy. Only 10% to 15% of all broodmares develop a pathologic persistent form of breeding-induced endometritis.[126] Attention should be given to identify and manage these mares appropriately in order to optimize reproductive efficiency.

43.30.1.10.4

CHRONIC DEGENERATIVE ENDOMETRITIS (ENDOMETROSIS)

Several treatments have been suggested for degenerative fibrosis of the endometrium, but consistent results have not been reported. Mechanical or chemical irritation of the endometrium has been used, but concerns that trauma to the endometrium may produce more scar tissue than repair have limited the popularity of such methods. Infusion of dimethyl sulfoxide (DMSO) into the uterine lumen has been shown to improve fibrosis in mares with chronic degenerative endometritis[178]; however, other researchers were not able to repeat these results.[179]

Prognosis for fertility after endometritis varies with the severity of inflammation and fibrosis and the inciting cause. Prognosis should take into account the age of the mare and the level of reproductive management, in addition to the cause and likely response to treatment.

43.30.2 Metritis

Metritis is classically defined as inflammation of all layers of the uterine wall. Metritis occurs in the first 2 weeks after foaling and commonly follows abortion, dystocia, and RFMs. In mares, metritis is often accompanied by endotoxemia and laminitis. Transluminal adhesions between endometrial folds may follow severe metritis.

43.30.2.1 Clinical Signs and Diagnosis

Metritis is characterized by uterine accumulation of postpartum secretions, bacteria, and the products of inflammation, with discharge from the cervix and possibly the vulva. Discharge is usually fluid and red-brown and may be fetid. Systemic signs of depression accompanied by neutropenia and leukopenia are apparent with development of endotoxemia. Differential diagnoses include normal lochia and causes of profound depression in the postpartum period as a result of uterine tears and abdominal catastrophes. 1441 1442

43.30.2.2 Treatment and Prognosis

Treatment is directed toward removing contamination and microorganisms from the uterus while providing systemic treatment for endotoxemia. Broad-spectrum systemic antibiotics, antiinflammatory drugs, and fluid therapy are indicated. Uterine contamination may be removed by gentle intraluminal infusion of warm water or saline and siphoning off of uterine contents. Vigorous lavage should be avoided, particularly during acute systemic disease. Prognosis depends on severity of clinical signs. If metritis is diagnosed quickly and treatment is instituted, prognosis for fertility and systemic health is good. Prognosis is guarded once endotoxemia and laminitis develop.

43.30.3 Pyometra

Pyometra in mares is an accumulation of purulent exudate in the lumen of the uterus. Impedance to mechanical uterine outflow, such as cervical fibrosis and adhesions of cranial parts of the tract ventrally into the abdomen, may contribute to the development of pyometra. If endometrial irritation causes release of endogenous endometrial PGF, diestrus will be shortened. In some mares, endometrial destruction is so severe that PGF release is inadequate and luteal life is prolonged.[92] A variety of bacteria may be involved, including *E. coli, Pseudomonas*, species, and *Streptococcus*, species. Cultures may be negative.

43.30.4 Clinical Signs and Diagnosis

A purulent vaginal or cervical discharge may be seen. The mare may demonstrate a short diestrus, a normal interestrous interval, or a prolonged diestrus. Occasional mares with pyometra have mild leukopenia and normocytic-normochromic anemia, secondary to mild suppression of erythropoiesis.[92] Transrectal palpation and ultrasonography reveal a fluid-filled uterus. The uterine wall may be thin and flaccid or thick.

43.30.5 Treatment and Prognosis

Treatment should involve correction of predisposing causes, fluid evacuation, and local antibiotic treatment. Evacuation of large amounts of fluid from the uterus may result in redistribution of fluid and circulatory shock. The mare should be monitored for signs of circulatory shock, and intravenous fluid may be administered during evacuation of large amounts of fluid from the uterus. The prognosis for life is excellent; however, the prognosis for return to normal fertility is guarded to poor because the conditions that predispose to development of pyometra in mares (cervical stenosis and adhesions) are difficult to treat and because severe endometrial destruction may develop. Endometrial biopsy should precede vigorous treatment. Hysterectomy should be considered if treatment is unsuccessful and if discharge is unacceptable or if adhesions impair athletic ability.

43.31 RUMINANTS

43.31.1 Parturition

Deliveries complicated by dystocia or RFMs may be followed by severe bacterial infections of the uterus. The most sanitary environment possible should be provided for calving. The use of a clean pasture may be most appropriate on some farms, whereas the use of roomy, well-bedded, indoor maternity pens that are cleaned after each delivery may be appropriate on others.

Cows with abnormalities around the time of calving such as hypocalcemia, dystocia, and RFMs are more likely to develop uterine infections than are cows that calve normally. Routine treatment of cows with antibacterial drugs and chemicals has not been shown to be beneficial and in some cases has reduced fertility. Postpartum uterine infections may be prevented, or the number of such infections reduced, by strict attention to sanitation in the calving environment and during assistance with delivery, along with proper management during the dry period.[180]

43.31.2 Bovine Uterine Infection

Bovine uteri are normally contaminated by a wide variety of microorganisms during the puerperium. Most of the organisms are transient residents of the reproductive tract and are soon eliminated from the involuting uteri of normal cows. *Arcanobacter (Actinomyces) pyogenes*, can persist in the uteri of cows and act with *Fusobacterium necrophorum*, and *Bacteroides*, species to cause uterine infections. Coliforms, *P. aeruginosa*, hemolytic streptococci, and gram-positive and gram-negative anaerobic bacteria are also frequently isolated from animals with postpartum uterine disease. *A. pyogenes*, and *Clostridium*, species occasionally colonize the postpartum uterus synergistically, causing severe gangrenous metritis. Other organisms that appear to have little effect on fertility may colonize the uterus and produce penicillinase, thus influencing the selection and route of administration of drugs used to treat uterine infections.[121]

43.31.2.1 Clinical Signs and Diagnosis

Lochia is normally expelled during the first 2 weeks after calving and may range from dark red or brown to white to clear. If uterine involution is delayed, discharge of lochia may continue until 30 days after calving. Discharge of lochia is not abnormal unless the fluid is fetid or the cow develops other abnormal clinical signs. Abnormalities of uterine involution cannot be diagnosed by palpation per rectum during the first

several days after calving when both normal and abnormal uteri are out of reach and cannot be safely retracted. By 10 to 15 days after calving the entire uterus can be palpated if involution is normal. Fluid should not be palpable within the uterine lumen by 14 to 18 days after calving. Gross reduction in size and histologic repair of the endometrium are complete in dairy cows by 40 to 50 days after calving.

Postpartum metritis in cows is characterized by the presence of variable amounts of lochia within the uterine lumen that may be discerned by palpation per rectum. A vaginal discharge is usually present, but it may become obvious during palpation. Septic metritis is characterized by clinical signs of toxemia that may include fever, depression, partial or complete anorexia, and laminitis. Milk yield is depressed, and cows may be unwilling or unable to rise. Some cases may be complicated by tenesmus. Vaginitis and cervicitis may accompany metritis. Discharges associated with septic metritis vary from scanty white mucus to copious amounts of red to red-black, watery, malodorous fluid. In some cases inflammation may spread through the uterine wall and cause perimetritis and peritonitis.[181] Septic metritis in ewes and does is characterized by fever, depression, anorexia, and tenesmus.

Endometritis in cattle is usually observed between 2 and 8 weeks after calving. Discharge can range from white pus to estrual mucus. Purulent exudate may be observed only with palpation or may be found in the cranial vagina and cervical canal on examination with a speculum. The history may indicate that the cow has failed to conceive after several services but the patient is otherwise healthy. 1442 1443

Culture of endometrial fluid is not usually done in individual cases of bovine uterine infection but may be indicated to determine the antibiotic susceptibility of microorganisms on a particular farm or as a part of the diagnostic plan when the incidence of postpartum metritis or endometritis increases suddenly.

Endometrial biopsies are rarely used in cows but have been recommended when complete evaluation is required of the reproductive tract of cows that do not conceive or that conceive but do not complete their pregnancies.[5]

43.31.2.2 Treatment and Prognosis

To be useful in treating uterine infections in cows, an antibiotic must be active against the primary uterine pathogens (*A. pyogenes*, and gram-negative anaerobes), in the presence of organic debris, and in the anaerobic environment of the postpartum bovine uterus.[182] Organisms infecting the uteri of cows are usually susceptible to penicillin, but during the first month after calving, contaminating microorganisms may produce penicillinase. Therefore penicillin is not likely to be effective if given locally during the early postpartum period. By 30 days after calving, organisms that produce penicillinase are usually eliminated from the uterus, and intrauterine treatment with penicillin may be beneficial. The daily intrauterine dose of penicillin required to reach the minimum inhibitory concentration of common bacteria such as *A. pyogenes*, is 1×10^6 IU.[182] Oxytetracycline is active against many of the microorganisms that infect the bovine uterus, and its activity is only slightly reduced by organic debris and absence of oxygen. Intrauterine treatment with administration of 4 to 6 g of oxytetracycline per day has been recommended. Some preparations of oxytetracycline irritate the endometrium, cervix, and vagina. Intrauterine antibiotic treatment of dairy cows results in residues in their milk.[183] For example, oxytetracycline has been found in milk from 44[184] to 96[185] hours after intrauterine administration.

Penicillin by systemic administration is effective for treatment of some uterine infections in cows. Daily doses of penicillin required to reach the minimum inhibitory concentration of *A. pyogenes*, are 10,000 to

20,000 IU/kg/day. Minimum inhibitory concentration of oxytetracycline for *A. pyogenes*, in the uterus is usually higher than the concentration that can be achieved by systemic administration of the drug.

Treatment of septic metritis should be directed toward controlling septicemia. Large doses of broad-spectrum systemic antibiotics are indicated, along with fluids and other supportive therapy. Attempts to remove RFMs or irrigate the uterus are contraindicated during the acute phase of the disease. After the patient has recovered from acute septicemia, intrauterine therapy may be considered.

43.31.2.2.1

ANTISEPTIC CHEMICALS

A variety of antiseptic chemicals have been infused into the uterine lumen of cows in attempts to treat metritis and endometritis, but few controlled trial evaluations are available. These are attractive as a way to avoid antibiotic residues in the milk intrauterine infusion.[186] Dilute solutions of povidone-iodine (one part povidone-iodine stock solution to 10 to 20 parts saline) have been suggested as being useful in treating fungal endometritis.[44] Povidone-iodine is generally available as a 10% solution with 1% free iodine (10,000 ppm of free iodine), so that a dilution of 20:1 saline:povidone-iodine yields a flush with 500 ppm of free iodine, which should be bactericidal.

43.31.2.2.2

UTERINE LAVAGE

Lavage of the uterine lumen with large volumes of warm saline (40° to 45° C [104° to 118° F]) removes accumulated fluid and debris. Uterine lavage has been used as an adjunct to antibiotic, antiseptic, and plasma treatment. Catheters designed for nonsurgical embryo recovery are suitable for uterine lavage. Saline is infused into the endometrial cavity in 0.5- to 1-L increments, allowed to reflux through the catheter, and collected for inspection. A milk hose and larger fluid volumes may be used in cattle with larger postpartum uteri, but care must be taken not to enter far into the uterus because it is friable and easily perforated. Massage or partial retraction of the uterus by palpation per rectum may be necessary to increase fluid recovery. The uterine lumen is lavaged repeatedly until the fluid returning through the catheter is no longer turbid.

43.31.2.2.3

PROSTAGLANDINS

In cows, repeated administration of PGF results in shortened estrous cycles and may mimic the shortened luteal phase of patients with acute endometritis. PGF therapy may be sufficient in mild cases of endometritis or may be used in combination with intrauterine or systemic therapy. In cases of chronic bovine endometritis, treatment with PGF one or two times at 10- to 14-day intervals decreased the number of days open.[187]

The prognosis in cows for recovery from endometritis is usually good if the condition does not progress to a more severe form of uterine disease. Septic metritis after dystocia or RFMs may result in permanent impairment of reproductive function, laminitis, or death of the patient in spite of aggressive therapy.

43.31.3

Pyometra

In dairy cows, pyometra is likely to develop in cows that ovulate before microorganisms that infect the uterus during the postpartum period are eliminated. The CL that develops after the first postpartum ovulation at

approximately 15 to 18 days after calving persists, possibly because the abnormal uterine contents suspend release of PGF from the endometrium or sequester it within the uterine lumen. The uterus is brought under the influence of progesterone, which depresses phagocytic activity of uterine neutrophils and closes the cervix, allowing the bacterial infection to persist.[188] Pyometra rarely endangers the general health or life of affected cows. Postcoital pyometra may be caused by *T. foetus*.,[189]

PGF is the treatment of choice for bovine pyometra. Treatment with PGF is followed in 3 to 6 days by uterine evacuation in 85% to 90% of treated cows. Response to PGF treatment may be raised with a second injection of PGF in 6 to 12 hours. After endometrial lesions are allowed to heal for 30 days, fertility is restored in most patients.

Treatment of cows with GnRH 2 weeks after calving improves fertility in some but not all situations. In herds with a high prevalence of postpartum uterine infections, treatment with GnRH may decrease fertility by inducing ovulation and CL development; thus the uterus is brought under the influence of progesterone before contaminating bacteria are removed, leading to pyometra.

43.31.4 Perimetritis

Perimetritis may occur in all species as a sequela to severe uterine infections, uterine rupture, penetration of the vagina during mating, traumatic insemination or obstetric procedures, and cesarean section.[102,190] Perimetritis is characterized by inflammation of the peritoneal surface of the uterus and may be accompanied by localized or diffuse peritonitis. Adhesions then develop between the uterus and other pelvic and abdominal organs.

1443

1444

43.31.4.1 Clinical Signs and Diagnosis

The clinical signs of perimetritis are those of peritonitis and may include fever, depression, partial or complete anorexia, stasis of the gastrointestinal tract, and evidence of abdominal pain. Abdominal pain is typified by colic in mares and by grinding the teeth (odontoprisis) in cows. In cows the condition should be differentiated from traumatic reticuloperitonitis, displacements of parts of the digestive tract, abomasal ulcers, postpartum metritis, and abdominal fat necrosis. Perimetritis in mares must be differentiated from other causes of severe abdominal pain. Antemortem diagnosis of perimetritis is difficult in sheep and goats that are presented mainly with fever, depression, anorexia, and odontoprisis.

43.31.4.2 Clinical Pathology

Cases of acute perimetritis are accompanied by leukopenia, neutropenia, and a degenerative left shift. Further evidence of peritonitis is obtained when peritoneal fluid is obtained by paracentesis and examined for its cellular and microbiologic content.

43.31.4.3 Treatment and Prognosis

The cause of perimetritis should be treated if possible. Cases of severe metritis should be treated appropriately and uterine ruptures sutured if possible. Repair of uterine ruptures inaccessible by flank incisions may be facilitated by intentional prolapse of the uterus after administration of epinephrine, provided the tear is not too close to the cervix (see next section). Treatment with broad-spectrum systemic antibiotics is indicated. Lavage to remove peritoneal exudate has been recommended but is difficult to accomplish,

especially in cows in which the rumen, abomasum, and greater omentum make ventral drainage almost impossible and in which fibrinous peritonitis with loculation of infection occurs rapidly. Other supportive treatments such as intravenous fluids and antiinflammatory drugs should be administered as indicated.

The prognosis depends on the severity of lesions. Fatalities can occur in spite of prompt treatment, and surviving animals may be infertile because of mechanical interference with gamete transport caused by adhesions between the genital organs and other pelvic and abdominal tissues. In general, the prognosis for fertility in affected animals is fair at best.

43.31.4.4 Prevention and Control

Perimetritis occurs sporadically in individual animals; therefore prevention depends on avoiding the causes. Immature females, especially heifers and fillies, should not be allowed at pasture with adult males, to prevent undesired mating complicated by penetration of the vagina. Traumatic obstetric, insemination, and uterine lavage procedures must be avoided. Uterine tears that occur at parturition must be sutured immediately. Postpartum metritis must be treated promptly and appropriately before it progresses to perimetritis.

43.32 SMALL RUMINANTS

Uterine infections may follow dystocia and RFMs in sheep and goats but are not frequently a cause of infertility because lambing and kidding are followed by a period of up to 6 months of sexual rest before the next breeding season. RFMs and metritis follow abortion in ewes caused by *Listeria monocytogenes, C. fetus*, subsp. *fetus*, and *Chlamydia psittaci*.,

Ewes and does affected with metritis are usually treated with systemic antibiotics such as penicillin or sulfamethazine. Early and aggressive treatment is indicated.[190]

43.33 CAMELIDS

43.33.1 Metritis and Endometritis

Camelids are induced ovulators, and females are usually receptive to males unless they are pregnant. Females do not, however, always have a preovulatory follicle present. Therefore it is frequently the case that females are bred at a time when they do not have a fertile follicle present. When camelids breed, the penis is inserted through the cervix and deep into the uterine horns. Unnecessary matings, or overbreeding, is the most important factor causing damage and contamination to the uterus.[191] Other major contributing factors include RFMs, rectal vaginal tears, and unsanitary obstetric manipulations.[191]

Chronic endometritis will often not cause evident clinical signs, whereas acute, postpartum endometritis may cause fever, depression, and signs of toxic shock.[191] A thick, mucoid lochial discharge is normal in the postpartum female for up to a week postpartum. Thin, watery, fetid discharge is a sign of endometritis.[191]

Transrectal ultrasonography and vaginoscopy are helpful in diagnosing endometritis and metritis. Inflamed, thickened uterine walls and hyperechoic, intraluminal fluid may be present on ultrasound examination. Vaginoscopy may reveal cervical discharge. Transrectal ultrasonography may usually be performed in llamas as

in horses or cattle. In alpacas, because of smaller size, an extension probe will be necessary to facilitate transrectal ultrasonographic evaluation.

Uterine culture and cytology samples from the llama may be obtained in methods similar to those in the mare and cow. A double-guarded swab prevents environmental contamination. In the alpaca the swab should be passed through the cervix via visualization using a vaginoscope. These diagnostics should be performed during the peak follicular phase to ensure ease of passage through the open cervix and more reliable test results.[191] The most common bacteria isolated from the uteri of camelids with endometritis are *E. coli, S. zooepidemicus*, β-hemolytic streptococci, *Enterococcus*, coagulase-negative *Staphylococcus, Proteus*, species, *Enterobacter aerogenes, K. pneumoniae*, and *A. pyogenes*,.[191]

Uterine biopsy can be a very useful diagnostic tool for evaluation of metritis and endometritis in camelids. Endometrial biopsy samples in llamas may be obtained as in the mare. The left horn is perhaps better to target unless a particular pathology is suspected in the right horn, because camelid pregnancies almost always occur in the left horn.[191] Pathologic changes, evaluation, and prognosis are all assumed to be similar to those in the mare.[191]

Treatment for endometritis and metritis is also similar to that described for the mare. Uterine lavage with a warm, isotonic saline solution and oxytocin injection (5 to 10 IU) are the major components of treatment. Intrauterine antibiotic infusion is done after uterine lavage. The most common antibiotics used are penicillin K (1.5×10^6 U), gentamicin sulfate (200 to 300 mg), and ceftiofur sodium (250 to 500 mg).[191] Antibiotics should be diluted in sterile water or saline (saline should not be used with ceftiofur) and given once daily for 5 to 7 days. Females should be evaluated after cessation of treatment and completion of 2 weeks of sexual rest.

Prevention of endometritis often requires a "minimum contamination breeding technique."[191] This entails monitoring follicular growth via transrectal ultrasound until the follicle is of preovulatory size, breeding only once, following breeding with an injection of hCG (750 IU) or GnRH, and administering an intrauterine infusion of antibiotics 24 hours after breeding. Females should be evaluated for pregnancy 12 to 14 days after breeding. 1444 1445

Further preventative measures include performing prebreeding examinations on all maiden animals to avoid breeding animals that are too young or do not have follicular activity; breeding only females exhibiting strong receptive behavior (as opposed to mere submissive behavior); performing complete gynecologic examinations of all females with a history of infertility, obstetric problems, or postpartum complications; and observing strict rules of hygiene during breeding and obstetric manipulations.[191]

43.33.2 Pyometra

Pyometra caused by delayed uterine involution may be observed shortly after parturition. Chronic pyometra is often associated with vaginal or cervical adhesions that may be the sequelae to trauma after dystocia or aggressive obstetric manipulation.[191]

43.34 ANATOMIC DEFECTS AS A CAUSE OF UTERINE INFECTION

The most common anatomic defect associated with genital infections is pneumovagina. Other defects include urovagina and perineal lacerations. These defects should be corrected to prevent contamination with environmental and fecal organisms.

43.35 ENDOMETRIAL CYSTS AND LACUNAE

43.35.1 MARES

Endometrial cysts and lymphatic lacunae are common degenerative changes of the endometrium that are more prevalent in mares older than 11 years of age than in younger mares.[192] Endometrial cysts can originate from endometrial glands or obstructed lymphatics. Glandular cysts are small (<10 mm) and are believed to be the result of periglandular fibrosis. Lymphatic cysts can reach several centimeters in diameter. The cause of lymphatic cysts is not fully understood, but lacunae are thought to arise after interference with normal lymph drainage from the genital tract.[5]

43.35.1.1 Clinical Signs and Diagnosis

Endometrial cysts can be visualized by ultrasonography or by hysteroscopy. Cysts may mimic pregnancy when mares are examined per rectum by palpation or ultrasonography.[193] Sequential examination reveals that size of endometrial cysts remains static, whereas amniotic vesicles enlarge. Large, discrete, fluid-filled cysts may be identified by palpation of the uterus per rectum. Smaller cysts and lacunae may be observed in endometrial biopsy sections. Uteri affected by lymphatic lacunae are enlarged and have a thicker wall than normal.

43.35.1.2 Treatment and Prognosis

Endometrial cysts do not require treatment unless they are suspected to interfere with pregnancy. Endometrial cysts have been suggested to cause embryonic death and abortion if large or numerous. However, one study failed to find an association between the presence or number of cysts and fertility.[192] Obliteration of endometrial cysts using endoscopic guided laser surgery removes the cysts permanently, but the long-term effect on fertility has not been critically evaluated. Needle aspiration, mechanical rupture of the cyst, uterine curettage, or intrauterine infusion of hypertonic saline solution have all been suggested to effectively remove endometrial cysts. However, the cysts often recur after treatment.

43.36 UTERINE PROLAPSE

Uterine prolapse occurs when the previously gravid uterine horn becomes invaginated after delivery of the fetus(es) and protrudes from the vulva.

43.36.1 MARES

Uterine prolapse is an uncommon sequela to normal foaling, dystocia, or RFMs in the mare. The tip of the previously gravid horn invaginates to form uterine eversion. Eversion is accompanied by pain and abdominal straining. The myometrium may contract around the ring of invaginated tissue. Transrectal palpation confirms the diagnosis, and the everted tissue may be replaced manually. Eversion may progress to complete uterine prolapse, accompanied by rapid onset of systemic signs.

43.36.1.1 Treatment and Prognosis

The prolapsed uterus should be washed with clean saline and replaced manually in the standing mare as rapidly as possible. Replacement is aided by sedating the mare and administering epidural anesthesia. The uterus should be supported on a clean sheet held at the level of the pelvis. The uterus should be replaced, beginning with the uterine body and working gradually, replacing the tip of the horns last. Correct positioning of the uterus is important to prevent the prolapse from recurring. Replacement should be followed by treatment with broad-spectrum antibiotics, antiinflammatory drugs, and intravenous isotonic fluids. Treatment with oxytocin (10 to 20 IU IM) facilitates uterine involution. Prognosis is related to development of sequelae such as uterine tears, metritis, and endometrial damage.[194]

43.36.2 RUMINANTS

In cows most cases of uterine prolapse occur within a few hours after calving. The condition is invariably associated with hypocalcemia, which results in lack of uterine tone and delayed cervical involution. In addition, dystocia frequently precedes uterine prolapse.

Elective uterine prolapse can be induced within 6 to 12 hours after calving by administration of epinephrine to relax the uterus for the repair of uterine tears. A 10-mL amount of epinephrine (1:1000) is diluted to 250 mL in sterile saline and administered slowly IV. After 100 mL of the solution has been given, the operator reaches through the cervix, grasps the uterine wall and caruncles, and everts the uterine horn toward the cervix. When sufficient uterine tissue has entered the cervical canal, the patient responds by straining, which assists in completion of the prolapse. Epidural anesthesia is administered to abolish further straining *after*, the prolapse is complete.

Uterine prolapse in does has been associated with dystocia, hypocalcemia, and lack of exercise.[5] The predisposing factors are probably similar for ewes.

43.36.2.1 Clinical Signs and Diagnosis

Clinical signs of uterine prolapse are obvious. The membranes may remain attached. Immediately after prolapse occurs the tissues are nearly normal, but within a few hours they become enlarged and edematous. The endometrium is usually contaminated with feces and bedding material. In some cases the prolapsed tissue may be lacerated or severely traumatized and may contain loops of intestines.

Clinical signs that may accompany uterine prolapse include straining, abdominal pain, restlessness, anorexia, and increased pulse and respiratory rates.[102] Parturient paresis is common in affected dairy cows. In most patients these signs are transitory, but shock may complicate some cases.

1445 1446

43.36.2.2 Clinical Pathology

Uterine prolapse in cows is frequently accompanied by hypocalcemia and a significant increase in the packed cell volume.[195]

43.36.2.3

Treatment and Prognosis

The prolapsed tissue should be protected from further damage by wrapping it in wet towels or covering it with a plastic bag. Beef cows should be restrained where they are found, to prevent trauma to the uterus or rupture of the large uterine vessels should an animal try to escape on arrival of the clinician. Treatment of hypocalcemia is usually indicated before replacement of the uterus if the cow is recumbent and semicomatose; otherwise calcium gluconate is administered after replacement. Epidural anesthesia is frequently (but not always) required.

The prolapsed tissue is washed with a mild presurgical scrub. The membranes are removed if they can be easily separated from the endometrium but are left in place if removal is difficult. Some clinicians recommend that cows stand during replacement, whereas others have found that the organ can be replaced in recumbent cows if the patient is placed on her sternum with the hind legs drawn straight out behind. The prolapse is placed between the extended limbs.[196] In fresh cases, replacement is relatively easy and is begun at the cervical pole of the organ; the dorsal and ventral parts are massaged alternately back into their normal position. After the ovarian pole has been replaced, the previously prolapsed horn must be straightened, and eversion of the uterus corrected. Administration of clenbuterol is reported to relax the uterus, facilitate replacement, and reduce the need for epidural anesthesia, but its use is illegal in the United States.[197] If the patient has been neglected, accumulated fluid must be reduced by lubricating the tissue with an emollient ointment then carefully but vigorously massaging the tissue from the ovarian pole toward the cervical pole. The hygroscopic action of sugar when applied liberally to prolapsed uteri is of limited value and vastly overrated.

Oxytocin is frequently administered to stimulate myometrial contractions after the uterus has been replaced. Metritis is a frequent sequela, and appropriate antibiotic treatment is indicated in most cases. Temporary closure of the vulva with heavy sutures after replacement is not necessary[102] but is practiced by many clinicians.[5] If replacement of the prolapsed uterus is impossible or the tissue is severely traumatized, amputation may be indicated; in this case it is important that the uterine arteries be double ligated.[198]

The prognosis varies but is generally favorable if there has been no serious damage to the uterus.[5,196] Fatalities can occur in cases complicated by shock or by rupture of large uterine vessels. The culling rate from infertility of cows with uterine prolapse is higher than that of their herdmates, and the calving interval is prolonged in affected cows. Barring hypocalcemia, the risk of uterine prolapse at a subsequent calving is no greater than for other cows in the herd.

43.36.2.4

Prevention and Control

Because the condition is associated with hypocalcemia in cows, provision of a properly balanced ration before calving is indicated. Although uterine prolapse can occur after an apparently normal delivery, it is more commonly associated with dystocia and forced extraction; therefore prolapse should be anticipated, and the dam observed so affected patients may receive prompt treatment.

43.36.3 CAMELIDS

Uterine prolapse in camelids usually is a consequence of dystocia, RFMs, or excessive obstetric manipulation. Treatment is the same as described for other species and includes gentle, clean manipulation of the prolapsed uterus, replacing the organ starting at the cervix. Replacement is easier with early cases. Difficulty increases and prognosis decreases greatly with chronicity.[9]

43.37 UTERINE TUMORS

Neoplasia uncommonly affects the uterus of domestic animals. Tumors may arise from within uterine tissues or metastasize from other organs.[11] Leiomyomas are usually benign and arise from the outer smooth muscle of the uterus without need for a preparatory event. The multicentric form of lymphosarcoma may affect the uterus of cattle. Lymphosarcoma also affects does, but a predilection for the uterus is not apparent. Carcinomas, chorionepitheliomas, fibromas, fibrosarcomas, rhabdomyosarcomas, and adenosarcomas are rarely reported.

Small tumors may escape detection, whereas larger ones may be palpable per rectum in mares and cows. Leiomyomas are not necessarily associated with reproductive failure, and tumors and fetuses can coexist. Uterine walls affected by lymphosarcoma may contain discrete neoplastic nodules or be diffusely infiltrated. Tumor masses must be differentiated from normal fetuses, mummified or macerated fetuses, placentomes, abscesses, and fat necrosis.

Solitary leiomyomas thought to interfere with fertility may be removed. Other forms of uterine neoplasia are usually not treated. The prognosis is generally poor.

43.38 SEGMENTAL DEFECTS

Segmental aplasia (white heifer disease) occurs sporadically in all breeds of cattle. In most cases the cranial parts of the genital tract (ovaries, uterine tubes, and cranial part of the uterine horns) are normal, and endometrial secretions from the parts of the uterine horns accumulate because normal drainage through the cervix is impeded. Various defects may be found in affected animals, ranging from nearly complete absence of tubular genital organs to an imperforate hymen that blocks secretion drainage from a normal genital tract.

43.38.1 Clinical Signs and Diagnosis

Segmental aplasia may be associated with a history of anestrus if fluid accumulation within the uterine horns interferes with release of PGF and luteolysis. Other presenting history may involve infertility or difficulty in AI. On palpation per rectum, various degrees of aplasia may be recognized. Fluid-filled parts of the uterine horns may suggest pregnancy, from which they must be differentiated. An imperforate hymen may bulge from the vulvar cleft and may be confused with vaginal prolapse, prolapse or eversion of the urinary bladder, cystic vestibular glands, or neoplasia of the vulva or vagina.

43.38.2 Treatment and Prognosis

The only form of segmental aplasia amenable to treatment is that in which an imperforate hymen occludes an otherwise normal tract. Incision of the hymen is followed by drainage of accumulated secretions and may allow the tract to function normally.

43.39 PARAMESONEPHRIC DUCT APLASIA

Aplasia of one paramesonephric duct leads to development of one uterine horn (uterus unicornis). The condition is relatively rare but does occur in cattle. Subfertility is the result of prolonged periods of anestrus caused by a persistent CL on the ovary ipsilateral to the missing uterine horn (no local luteolytic signal). The condition can be managed with exogenous PGF in the hope that ovulation will occur on the intact side. Alternatively, the unaccompanied ovary can be surgically removed. 1446 1447

43.40 UTERUS UNICORNIS AND UTERUS DIDELPHIS

The caudal parts of the paramesonephric ducts may not fuse properly in cattle, causing duplication of various parts of the caudal tubular tract. Abnormalities of fusion are most common in and around the cervix. The entire cervix may be duplicated; or the cervix and vagina may be normal, with the exception of the presence of a band of tissue extending dorsal to ventral across the external os of the cervix. Partial failure of fusion may involve a part of the cervix, and the affected animal may possess a single uterine body and internal cervical os, duplication of a part of the cervical canal, and a doubled external cervical os. Uterus didelphis results when the cervix and uterine body are completely duplicated. Affected cows may conceive after natural service or if artificially inseminated through the cervix and uterine horn ipsilateral to the ovary about to ovulate. Affected animals may be unable to carry a pregnancy to term because of lack of placental attachment in the nongravid horn.

43.41 HYDROMETRA (PSEUDOPREGNANCY IN GOATS)

Hydrometra occurs sporadically in goats and is characterized by accumulation of several liters of clear fluid within the uterus, abdominal distention, persistence of a CL, and subsequent anestrus.[5] It is most common in pet and dairy goats that are housed separately from males and therefore experience estrous cycles without the opportunity to conceive. Previous breeding is not necessary, but the condition may develop after mating, and does are frequently assumed to be pregnant. It also can occur after early embryonic loss in goats or sheep. The cause of hydrometra is unknown, but a deficiency in production or release of PGF from the endometrium has been postulated, as has exposure to phytoestrogens. The clinical signs of hydrometra mimic those of pregnancy. The diagnosis is suspected if the goat fails to show estrus when it cannot possibly have been bred but is in a herd where heat detection is good. Serum progesterone concentrations are elevated, and abdominal enlargement suggestive of pregnancy may occur. Results of the urinary estrone sulfate test for pregnancy are negative. Amplitude-depth ultrasound for pregnancy is positive because of fluid in the uterus. Rectal Doppler may indicate increased blood flow to the uterus, but no fetal heart sounds are heard. Real-time ultrasound reveals fluid but no fetus or caruncles in the uterus. The animal should be rechecked if fewer than 40 days have elapsed since the last possible breeding. In advanced hydrometra, large fluid-filled compartments are seen separated by undulating tissue walls, which represent the uterus coiled back on itself. The fluid is cloudy and flocculent if aspirated through the abdominal wall. Spontaneous correction is common and varies from red discharge suggestive of early abortion to expulsion of accumulated fluid approximately 150 days after an infertile mating, so-called

"cloudburst." No fetus or placenta is passed. Treatment of false pregnancy is with prostaglandin. The clinician needs to keep in mind that this will abort the goat if it has a true pregnancy. An initial dose of 5 to 10 mg of dinoprost (Lutalyse) or 125 to 250 mcg of cloprostenol (Estrumate) is given and repeated in 12 days. Estrus and emptying of the uterus occur in 1.5 to 4 days. Oxytocin (50 IU bid for 4 days) will cause CL regression, but treatment with oxytocin is normally reserved for goats that still retain fluid in the uterus after prostaglandin therapy. The doe frequently becomes pregnant within a few days to weeks after termination of a false pregnancy if a buck is available. Sometimes hydrometra recurs. Suggestions for prevention have included selenium supplementation and breeding on the first heat of the season. The prevalence is probably increased in herds where breeding is delayed in order to obtain winter milk and in does manipulated hormonally to breed out of season. Routine pregnancy diagnosis of goats with real-time ultrasound should be advised to permit rebreeding during the same season.

43.42 CERVICAL ABNORMALITY

43.42.1 Cervicitis

Inflammation of the cervix usually accompanies endometritis and vaginitis and is frequently secondary to trauma associated with dystocia and obstetric operations. The mucus-secreting epithelium of the cervix is more resistant to bacterial infection than is the epithelium of the uterus and vagina.

43.42.1.1 MARES

The equine cervix is a straight tube made up of layered circular and longitudinal muscle. During estrus it relaxes, and the external os lies on the floor of the anterior vagina. During diestrus or pregnancy, under the influence of progesterone, the cervix is closed and the external os is elevated off the vaginal floor. Cervicitis or inflammation of the cervix may be iatrogenic or may occur secondary to trauma associated with parturition or dystocia or as an extension of vaginitis or endometritis. Endometritis and infertility follow if the cervix lacks anatomic integrity.

43.42.1.1.1 Clinical Signs and Diagnosis

Infertility and history of an inciting cause such as urine pooling or dystocia may be the only signs of cervicitis in the mare. Cervical hyperemia and edema may be apparent on speculum examination in acute cervicitis. In more chronic injuries, direct digital examination of the cervix of the mare in diestrus may reveal transluminal adhesions or anatomic defects.

For treatment and prognosis in mares, see discussion under Ruminants later in this section.

43.42.1.2 RUMINANTS

Similarly, in cows cervicitis is secondary to uterine infections and follows trauma associated with parturition and obstetric manipulations. Infection is usually caused by microorganisms normally present in the cranial vagina such as *E. coli*, streptococci, staphylococci, and *A. pyogenes*., Occasionally infection with anaerobic bacteria complicates cervicitis and results in severe toxemia.[102,199]

Cervicitis in does and ewes is uncommon but may occur secondary to vaginal and uterine infections and obstetric trauma.

43.42.1.2.1 Clinical Signs and Diagnosis

Examination of cows with a vaginal speculum reveals swelling and edema of the external cervical os. The mucous membrane is hyperemic and inflamed. Mucopurulent exudate may be present in the cervical canal or in the cranial vagina. Hypertrophy of the cervix is common in *Bos indicus*, breeds and their crosses and may be a normal finding; therefore cervical size as detected by palpation per rectum may or may not indicate inflammation. Inflammation of the cervix without contemporary endometritis may not affect fertility. Cervicitis may occur in pregnant cows.

1447

1448

The clinical signs of cervicitis in does and ewes are similar to those in cattle and must be observed with a small vaginal speculum.

43.42.1.2.2 Treatment and Prognosis

Most cases of cervicitis resolve spontaneously when coexisting endometritis and vaginitis improve. Exudate can be flushed from the cervical canal and cranial vagina with warm saline lavages, and a nonirritating antibiotic ointment applied to the affected tissue. Caustic chemicals should not be placed in contact with the cervical mucosa. Aggressive treatment with systemic antibiotics is indicated in cases complicated by infection with anaerobic bacteria.

The prognosis for most cases of simple cervicitis is fair to good. However, inflammation of the cervix in mares may progress to more severe cervical abnormalities. Cervical damage is a serious threat to future reproductive performance in mares. Anaerobic infections of the cervix may be fatal.

43.42.1.2.3 Prevention and Control

Obstetric manipulations and operations must be temperate. When the cervix does not properly dilate during parturition, a cesarean section is preferred over forced extraction.

43.43 CERVICAL LACERATIONS

43.43.1 MARES

Cervical lacerations are most often seen after dystocia. Cervical lacerations may result in adhesions and a nonpatent cervix or in a failure to seal the uterus during diestrus or pregnancy. Cervical adhesions in combination with endometritis are a common cause of pyometra in the mare.

43.43.1.1 Clinical Signs and Diagnosis

Cervical lacerations can be diagnosed by vaginoscopy and digital examination of the cervix. A digital examination of the cervix is often necessary to evaluate the degree and severity of the laceration. Evaluation of the ability of the cervix to close adequately is best performed during diestrus.

43.43.1.2 Treatment and Prognosis

If cervical lacerations are diagnosed shortly after parturition, antimicrobial ointment should be applied frequently to the lesion. Early signs of adhesions should be broken down until the tissue is healed. If the laceration results in an incompetent cervix, it should be corrected surgically. Although surgical repair of cervical lacerations has resulted in restored fertility in many mares, the condition is likely to recur at the time of the next parturition. Embryo transfer should be considered if allowed by the breed registry.

43.44 VAGINAL ABNORMALITIES

43.44.1 Pneumovagina

43.44.1.1 MARES

Pneumovagina is characterized by aspiration of air containing feces and microorganisms into the vagina. Pneumovagina is secondary to changes in perineal conformation, which include cranioventral displacement of the reproductive tract, loss of integrity of the vestibulovaginal sphincter, and loss of integrity of the vulvar labia. These changes occur more commonly in older, multiparous mares and those that have had perineal lacerations. Pneumovagina is a common antecedent to infertility.

43.44.1.1.1 Clinical Signs and Diagnosis

In the normal mare the anus is positioned directly dorsal to the vulva; the perineal body between the dorsal vulva and the anus is thick, muscular, and well formed; the vestibulovaginal sphincter is well formed; the vulva has a vertical alignment; 80% of the vulval labia lies below the floor of the pelvis; and the vulvar labia form a seal. Mares in which the vulva tilts horizontally at its dorsal aspect, the perineal body is thin, and the vulval labia do not form a seal are prone to pneumovagina in cases in which the anus lies rostral to the vulva. A scoring system has been developed to evaluate the perineal conformation in mares.[124] The system uses Caslick's index, which equals the distance (cm) between the dorsal commissure and the pelvic floor multiplied by the degrees of declination of the vulvar lips. Mares with Caslick's index above 150 were found to have subnormal pregnancy rates. Affected mares aspirate air on exercise or when the vulval labia are parted. Aspirated air may be noted on transrectal palpation or vaginal speculum examination. Signs of secondary changes such as vaginitis, cervicitis, or endometritis may be apparent.

43.44.1.1.2 Treatment and Prognosis

Treatment of pneumovagina should be directed toward correcting defective perineal conformation. Cranioventral displacement of the reproductive tract in aged mares may be irreversible. Perineal confirmation in thin mares is often improved by increasing the mare's body condition. Pneumovagina is often successfully corrected by surgical closure of the dorsal vagina via Caslick's operation. Secondary changes should be treated as described elsewhere. Prognosis for correction of pneumovagina is excellent; however, prognosis for fertility depends on the extent of secondary changes.

43.44.2 Urovagina

43.44.2.1 MARES

In normal, young mares the vagina slopes craniodorsally and is largely contained within the pelvis. With aging and repeated pregnancy, the cranial vagina may slope cranioventrally and fall below the level of the pelvic floor. Under these conditions urine collects in the anterior vagina, where it is spermicidal and may predispose to cervicitis and endometritis.

43.44.2.1.1 Clinical Signs and Diagnosis

In mild cases a history of infertility may be the only indicator of urovagina. In more severe cases, urine dribbles from the vulva at rest or during exercise and may accumulate inside the hind limbs. Speculum examination reveals a cranioventral slope of the vagina, variable inflammation of the cranial vagina and cervix, and a pool of urine in the ventral vaginal fornix. Urovagina may occur intermittently or only during estrus.

43.44.2.1.2 Treatment and Prognosis

Surgical procedures to prevent the anterior flow of urine include urethral extension[200] and vaginoplasty.[201] Prognosis depends on the severity of secondary endometritis and the success of surgery.

43.44.2.2 Vaginitis

Vaginitis may occur as a result of ascending infection or exposure to irritants, or secondary to pneumovagina, urovagina, perineal laceration, rectovaginal fistulas, breeding, endometritis, abortion, parturition, or dystocia. Occasionally, traumatic wounds may be infected with clostridial or anaerobic organisms; however, most infection is nonspecific.

43.44.2.2.1 Clinical Signs and Diagnosis

Signs may vary from hyperemia evident on speculum examination to mucopurulent exudation from the vulva. Severe trauma and infection may be followed by necrotic vaginitis with tenesmus, fetid discharge, elevated tail, swollen vulva, and systemic signs. Rapid formation of adhesions follows necrotic vaginitis. Metritis, RFMs, and uterine tears also may show systemic signs and vaginal discharge.

43.44.2.2.2 Treatment and Prognosis

The inciting cause should be treated. Animals with mild vaginitis may recover spontaneously, whereas moderate cases require local lavage with dilute antiseptic or antibiotic solutions. Fertility is unaffected in mild vaginitis without extension, and prognosis is good. Severe, necrotic vaginitis is treated with systemic antibiotics, analgesics, and antiinflammatory agents. Caslick's surgery may be necessary to prevent aspiration of air. Local application of antibiotic and steroid-impregnated ointments may help prevent adhesions. Prognosis for severe vaginitis is guarded. Vaginal stenosis and adhesions may follow vaginitis.

43.44.2.2.3 Prevention and Control

Nonspecific vaginitis may be prevented by preventing or reducing trauma to the vagina. Clinicians should elect appropriate methods for relief of dystocia and apply extractive force to fetuses judiciously.

43.44.2.3 Infectious Pustular Vulvovaginitis

43.44.2.3.1 COWS

Infectious pustular vulvovaginitis (IPV) affects cattle and is caused by bovine herpesvirus 1, also the cause of infectious bovine rhinotracheitis (IBR),[202] although the two strains are genetically distinct.[203] Therefore the respiratory and genital forms of the disease rarely occur concurrently, and abortions usually do not follow an outbreak of the genital form of the disease. IPV is spread by coitus and mechanical means and may affect unbred heifers. The incubation period of IPV is short (1 to 3 days), and the infection spreads rapidly through the herd, affecting 60% to 90% of the animals. IPV is not common.

43.44.2.3.1.1 Clinical Signs and Diagnosis

Early in the course of the disease IPV is characterized by a mucopurulent vaginal discharge, inflammation of the vaginal and vulvar mucosa, and painful urination. Pustules develop over lymphoid follicles and progress from small (<3 mm) ulcers to coalescing erosions. The virus causes inflammation of the penis and prepuce (balanoposthitis) leading to considerable pain. Therefore animals of both sexes with IPV are reluctant to mate. The clinical signs subside in 10 to 30 days, leaving the recovered animals with transient immunity. Early in the course of IPV, lesions may be similar to those of granular vulvitis (see later section), but the lesions of IPV rapidly become more severe. Vulvovaginitis caused by *Haemophilus somnus*, should be a differential diagnosis.

43.44.2.3.1.2 Treatment and Prognosis

Treatment of IPV is usually not required, although lavage of the vagina with dilute antiseptic solutions and emollients has been recommended. Mating among infected animals should be suspended until the disease subsides. The prognosis for recovery is excellent.

43.44.2.3.1.3 Prevention and Control

Vaccination against IBR is not likely to be beneficial in the face of an outbreak, but cattle may be protected if they are vaccinated before exposure. The IPV virus may survive in cryopreserved semen used for AI; therefore semen donors and semen should be free of the virus. Genital carriers may be responsible for sporadic outbreaks of IPV.

43.44.2.4 Vaginal Varicose Veins

43.44.2.4.1 MARES

Vaginal varicose veins are common in older mares. In most cases the condition is not associated with clinical signs, but affected mares may exhibit vaginal hemorrhage. A thorough examination of the reproductive tract is necessary to determine the origin of the bleeding.

43.44.2.4.1.1 Clinical Signs and Diagnosis

Clinical signs of varicose veins vary from no signs to persistent and profuse vaginal hemorrhage. Vaginoscopy or fiber endoscopy of the vagina reveals varicose veins in the vagina or the vestibulovaginal transverse fold. Vaginal hemorrhage from varicose veins should be differentiated from vaginal trauma and premature separation of the placenta in periparturient mares.

43.44.2.4.1.2 Treatment and Prognosis

Most mares with vaginal varicose veins do not require treatment. Surgical ligation, treatment with phenylephrine HCl cream,[204] or laser surgery of the veins may be necessary in cases of severe bleeding. The short-term prognosis after surgery is good, but the condition often recurs.

43.44.3 VESTIBULAR AND VULVAR ABNORMALITIES

43.44.3.1 Coital Exanthema

43.44.3.1.1 MARES

Coital exanthema is caused by equine herpesvirus 3 (EHV-3) and is a venereally transmitted dermatitis of the genital region of mares and stallions.[205,206]

43.44.3.1.1.1 Clinical Signs and Diagnosis

The disease is recurrent, is usually mild and transient, and affects the vulva and perineum of mares and the penis and prepuce of stallions. Lesions are initially small papules that rapidly progress to pustules and then ulcers. Lesions may rarely appear on the conjunctiva, lips, nares, and mucosa of the upper respiratory tract. Rare secondary bacterial infection and systemic signs occur. Intranuclear inclusion bodies are apparent in epithelial cells on histologic sections taken from the active edge of ulcers. Coital exanthema does not affect fertility in mares, but libido may be decreased in affected stallions because of pain during coitus.

43.44.3.1.1.2 Treatment and Prognosis

Lesions usually heal spontaneously within 14 days, leaving depigmented spots. Treatment is unnecessary unless secondary bacterial infection occurs. There is no available vaccine for EHV-3. Sexual rest until the lesions are healed is recommended to prevent further spread of the disease. Prognosis is excellent.

1449

1450

43.44.3.2 Granular Vulvitis

43.44.3.2.1 COWS

Granular vulvitis may occur in females of all domestic species but is most significant in cattle.[11] The disease is characterized by development of granules or papules in the vulvar mucosa accompanied by genital discharge. Infertility may or may not be a feature of the syndrome. Vulvitis may be secondary to nonspecific vaginitis.[102] *H. somnus*,[207] and *Mycoplasma bovigenitalium*,[5] have been isolated from cattle with vulvitis, but their role in infertility is not well defined, and there may be differences in pathogenicity among strains of the organisms. *Ureaplasma diversum*, has been isolated from cases of granular vulvitis in cows and ewes and may be associated with infertility when the organism is transferred into the uterus during AI.[5]

43.44.3.2.1.1 Clinical Signs and Diagnosis

Granular vulvitis is characterized by the formation of raised granules or papules in the vulvar mucosa and around the clitoris with variable amounts of mucopurulent exudate. In the mild form of granular vulvitis associated with *U. diversum*, only a few granules develop, and the infection has minimal effect on fertility. However, acute severe cases are characterized by hyperemia of the vulva, a profuse mucopurulent discharge, and depressed fertility. Purulent discharge during the acute phase persists for 3 to 10 days, after which the disease becomes chronic. In chronic cases the lesions are reduced in severity, and there is little or no purulent discharge. The chronic form may persist for several months, and the disease may become enzootic in some herds. The clinical signs of granular vulvitis may be similar to early signs of IPV.

43.44.3.2.1.2 Clinical Pathology

Samples for microbiologic culture should be obtained from the vulva, cervicovaginal mucus, and uterus. Use of a transport medium for submission of samples to a laboratory is mandatory. The organisms may be eliminated before the samples are obtained, yielding false-negative results. Conversely, microorganisms incriminated as causing granular vulvitis may be isolated from the genital tracts of normal animals.

43.44.3.2.1.3 Treatment and Prognosis

Most cases of nonspecific vulvitis resolve spontaneously. Infertility associated with *U. diversum*, infections is treated by preventing transfer of organisms to the uterus by using double-sheathed AI

instruments. Natural breeding should be suspended. In addition, infusion of 1 g of tetracycline or spectinomycin in a nonirritating vehicle into the uterus 24 hours after breeding has been recommended to reduce the population of organisms that may have been transferred to the uterus. Local treatment of vulvar lesions with tetracycline or spectinomycin has also been suggested.

43.44.3.2.1.4 Prevention and Control

In chronically infected herds, fertility rates may approach normal if double-sheathed AI instruments are used and affected cows are treated with appropriate antibiotics.

43.44.3.3 Ulcerative Dermatosis Genital Lesions

43.44.3.3.1 SMALL RUMINANTS

Ulcerative dermatosis is a venereal disease of sheep caused by a parapoxvirus similar to but distinct from the virus that causes contagious ecthyma.[7,102] The disease is characterized by ulceration of the skin and mucous membranes of the vulva of ewes and penis and prepuce of rams. Lesions also occur on the lips, nares, feet, and legs. The lesions are painful, and affected animals avoid coitus. The disease subsides in 7 to 10 days.

Because of its viral cause, no specific treatment is available for ulcerative dermatosis.[7] Symptomatic treatment with local astringent and antiseptic ointments has been suggested. Morbidity of 15% to 20% is expected, although up to 60% of a flock may be affected. Mortality is low if the animals are otherwise healthy.

No vaccine is available. Males with the disease should not be used for breeding.

43.44.3.4 Abnormal Labial Approximation

43.44.3.4.1 MARES AND COWS

The most common anatomic defect of the vulva of mares and cows is abnormal labial approximation, which leads to pneumovagina and subsequently to infertility.[44] The defect may be the result of imperfect conformation or traumatic insult to the vulva. Abnormal labial approximation is treated with Caslick's surgery or one of its modifications.

43.44.3.5 Persistent Hymen

In the developing embryo, failure of cannulation of the urogenital sinus by the mesonephric duct system results in absolute or partial occlusion of the vestibulovaginal junction. Total occlusion causes accumulation of endometrial and cervical secretions cranial to the obstruction, and occasionally the membrane may appear at the vulva. Partial occlusion may be noted only as an obstruction to breeding or during speculum examination. The membrane may be manually ruptured or incised. Prognosis is excellent.

43.44.3.6 Clitoral Hypertrophy

Clitoral hypertrophy may be a feature of intersex conditions, may occur in filly foals whose dams received progestins during pregnancy, or may follow administration of anabolic steroids.[64] Hypertrophy may persist after cessation of steroid treatment. In cows it may be associated with freemartinism.

Vulvar wattles in cattle may superficially appear similar, but the elongated epithelial structure does not involve the clitoris.

43.44.3.7 Neoplasia

Melanomas and squamous cell carcinomas (SCCs) are the most common neoplasms affecting the perineum, anus, and vulva of gray- and light-skinned horses, respectively.[208] Lesions are usually proliferative and may have surface ulceration, hemorrhage, and infection. Lesions should be differentiated from habronemiasis, granulation tissue, and sarcoids. Treatment is surgical removal. Sarcomas and melanomas may metastasize. Viral fibropapillomas are the most common tumors affecting the vulva of cattle.[11] SCCs may be seen in all species and may be more common in white-skinned animals exposed to long periods of solar radiation.[209]

Vulvar neoplasia is characterized by variable degrees of tissue proliferation. The surface of SCCs and fibropapillomas may be ulcerated, necrotic, and fly-blown. In cows squamous metaplasia of the nonpigmented skin of the vulva is frequently a precursor of squamous cell carcinoma of the vulva. Vulvar neoplasia must be differentiated from other causes of tissue proliferation, habronemiasis in mares, and ectopic mammary tissue in does.[5] Neoplasia of the vulva and vestibule is diagnosed by biopsy of the tumor.

Surgical excision is the treatment for most neoplasms of the vulva.[208] Viral fibropapillomas regress spontaneously after a period of several months. Recurrence and metastasis may occur.

1450

1451

43.44.3.8 Ectopic Mammary Tissue

Ectopic mammary tissue has been described in does and is characterized by swelling of the vulvar lips.[5] The abnormal enlargement begins before each parturition and persists for approximately 2 months. The condition is benign unless the tissue enlarges sufficiently to interfere with evacuation of feces or urine. Milk may be aspirated from the mammary tissue, and the condition may be confirmed by biopsy.

43.45 ABORTION

43.45.1 MARES

Information on the major causes of abortion in horses is summarized in Table 43-7.

43.45.1.1 NON-NONINFECTIOUS CAUSES

43.45.1.1.1 Twin Pregnancy

The incidence of abortion caused by twin pregnancy has decreased greatly because of widespread use of ultrasound in diagnosing early pregnancy in mares. Twin pregnancies are routinely detected as early as 12 to 14 days, at which time the twins can be manually reduced to a singleton pregnancy (discussed later). However, despite the overall decrease in the number of twin-related abortions, twinning still remains an important noninfectious cause of abortion in the mare.[210] The mare is unable to successfully support two fetuses to term and only in very rare cases (<2%) is able to carry both fetuses to term and deliver without dystocia.[211] It is much more common for the mare to have a natural reduction to a singleton pregnancy during the embryonic stage or to abort the pregnancy after the fetal stage.[212,213] Some breeds more commonly than others are diagnosed with twins during the embryonic stage (e.g., thoroughbreds have 20% to 30% double ovulations and 10% to 15% diagnosed twin pregnancies).

43.45.1.1.1.1 Clinical Signs and Diagnosis

Mares should be evaluated with transrectal ultrasound 12 to 14 days after documented ovulation during a breeding cycle. The uterus should be carefully scanned from the tip of one horn to the other and along the uterine body to the cervix. Equine embryos at this stage are highly mobile within the uterus and may be located anywhere within the uterus. Increased uterine edema and fluid within the uterine lumen are often negative signs of pregnancy, but pregnancy should not be ruled out until the entire uterine tract has been scanned for the presence of embryos. After one embryo is found, the remainder of the uterus still must be visualized to ensure the absence of a twin. The embryo proper per se is not visible at this stage of pregnancy, but the embryonic vesicle is easily visualized. Care must be taken not to confuse endometrial cysts with embryos, which sometimes can look deceptively similar. It is very helpful to have scanned the mare's uterus with ultrasound before breeding to document the size and location of endometrial cysts.

Table 43-7 Major Causes of Infectious Equine Abortion

Cause and Common Names	Usual Stage of Gestation	Major Fetal Lesions	Diagnostic Tests
Equine herpesvirus 1 (EHV-1)	Seventh month to term	Pulmonary edema, multifocal hepatic and pulmonary necrosis, intranuclear inclusions	Histopathology, virus isolation, fluorescent antibody test, fetal serology
Equine viral arteritis (pestivirus)	5–10 months	Myocardial arteritis	Histopathology, virus isolation, PCR, serology
Nocardioform actinomycete	Mid to late gestation	Characteristic placentitis located ventrally in the uterine body and at the base of the uterine horns	Culture
Streptococcus zooepidemicus,	Any stage	Placentitis with or without inflammation in fetal tissues	Histopathology, culture
Mycotic abortion, *Aspergillus*, and other species	Latter half (often near term)	Placentitis, fetal bronchopneumonia	Histopathology, fungal culture
Leptospirosis	Seventh month to term	Icterus and autolysis	Culture, immunofluorescence, serology

PCR, Polymerase chain reaction.

43.45.1.1.1.2

Treatment and Prognosis

If twins are confirmed before 16 days of pregnancy, the best way to treat the mare is to manually crush one of the vesicles. This is done by visualization of the twins using transrectal ultrasound and spatially separating them from each other within the uterus. One twin is moved away from the other to the tip of a uterine horn where it is crushed manually. The remaining embryo should be evaluated 1 to 2 days later to determine its status. Survival of the remaining embryo is greater than 90% when twin reduction is performed in this manner before day 20.[214]

It is the established practice of some veterinarians to treat mares with a nonsteroidal antiinflammatory agent (e.g., flunixin) and/or altrenogest after a twin-crush procedure. The reasoning behind this practice is that manual stimulation of the uterus may cause a release of oxytocin, signaling a prostaglandin cascade that will result in luteolysis and complete pregnancy loss. There have been no studies performed to support this theory; to the contrary, other studies have shown that the release of prostaglandin after the routine twin-crush procedure does not cause a drop in progesterone and that supplementation with antiinflammatory drugs or progesterone makes no difference in the outcome.[214,215]

Other techniques described for reduction of twins to a single embryo include transvaginal, ultrasound-guided fetal aspiration[216]; transcutaneous, ultrasound-guided fetal intracardiac injection of procaine penicillin or potassium chloride[217]; and craniocervical dislocation.[218] The success of these techniques is lower than that of manual crush, and they are performed later in gestation, after the window for manual crushing has been missed. These are all specialty techniques and are beyond the scope of this chapter. 1451 1452

43.45.1.1.2

Other Noninfectious Causes of Equine Abortion

In a survey of causes of equine abortion in the United Kingdom from 1988 to 1997, nearly 39% were caused by umbilical cord pathology.[219] Most of the cases (35%) resulted from torsion of the umbilical cord. Twisting of the umbilical cord is common in equine fetuses and often is not pathologic. A diagnosis of abortion caused by umbilical torsion should be made only if localized swelling and discoloration accompany the twisting. Congenital abnormalities may cause abortion. The most common congenital abnormality in equine fetuses is contracted tendons, accounting for 5% of abortions in a study from the United States.[210] Fetuses that implant in the uterine body instead of the base of one of the horns develop placental villous atrophy and usually abort, accounting for 2% of abortions in the same study.

43.45.1.2

INFECTIOUS CAUSES

43.45.1.2.1

Placentitis

Placentitis is the leading cause of equine late-term pregnancy loss in the United States.[210] Bacterial organisms most commonly cultured from aborted fetuses include *Streptococcus*, species, *E. coli, Pseudomonas*, species, *Klebsiella*, species, *Staphylococcus*, species, and *Leptospira*, species. Nocardioform actinomycetes are an important cause of placentitis in central Kentucky and have recently been reported in Florida.[220] The route of infection and the pathophysiology of *Nocardia*, abortions are poorly understood. *Aspergillus fumigatus*, and *Mucor*, species are the most commonly diagnosed causes of mycotic abortion in mares. Fungi cause 5% to 30% of infectious equine abortions.[5]

The route of placental infection is most commonly ascending via the cervix, which results in loss of chorionic villi around the cervical star. In addition to loss of chorionic villi, additional allantochorionic lesions may include nodular cystic allantoic masses, edema, necrotic areas of chorion, and necrotic mucoid exudate coating the chorion. Hematogenous placentitis shows a more generalized, diffuse loss of villi.[210] The distribution of the avillous chorionic lesion classically noted in mares with ascending or hematogenous placentitis does not fit the pattern noted with nocardioform placentitis. Mares with nocardioform placentitis classically show a loss of chorionic microvilli in a focal area around the base of the uterine horns. It has been postulated that the pathogen is present or introduced in the mare at the time of breeding and settles in the ventral aspect of the uterus, where it causes the infection. This hypothesis is not proven, though it is very likely that the nocardioform organisms are from the environment. Various nocardioform organisms have been reported in the soil in countries across the globe, although the pathogenicity of most of these organisms is not determined. The pathogenesis of nocardioform placentitis is still unresolved. Nocardioform organisms isolated from equine placentas include *Amycolatopsis*, species and *Crossiella equi*.,[220–223] Nocardioform placentitis often results in abortion or premature delivery.[210]

43.45.1.2.1.1

Clinical Signs and Diagnosis

Mares that abort because of placentitis often show clinical signs of pending abortion before the actual pregnancy termination. Premature udder development and vaginal discharge are common signs of pending abortion caused by placentitis. Transrectal ultrasonography of the allantochorion in an area close to the cervix is useful to detect early signs of placentitis and impending abortion (Fig. 43-8).[224] Ultrasound evaluations may reveal hyperechoic fetal fluids, placental separation, increased or decreased fetal heart rates (normal range 75 ± 7 bpm[225]), and thickening of the combined thickness of the uterus and placenta (CTUP). Consistently low or high fetal heart rates are associated with fetal stress. Foals experiencing fetal distress often become bradycardic initially and then become tachycardic in the terminal phase of life.[226,227] Serial examinations should be performed to verify fetal well-being or distress. Mares considered "at risk" for pregnancy loss are often examined on a daily basis. Fetuses experiencing distress are often evaluated several times a day. Normal measurements of CTUP have been established (Fig. 43-9).[228,229] Mares with placentitis may show increased CTUP, edema of the allantochorion, and separation from the endometrium. A 5-MHz linear transducer should be used for transrectal ultrasonography. The transducer should be positioned 1 to 2 inches cranial to the cervical-placental junction and then moved laterally until a major uterine vessel (possibly the middle branch of the uterine artery) is visible at the ventral aspect of the uterine body.[228] The CTUP should then be measured between the vessel and the allantoic fluid (see Fig. 43-5). It is important to obtain all CTUP measurements from the ventral aspect of the uterine body, because physiologic edema of the dorsal aspect of the allantochorion has been noted in normal pregnant mares during the last month of gestation. 1452 [228] In addition, care should be exercised to be certain that the amniotic membrane is not adjacent to the 1453 allantochorion, because this may result in a falsely increased CTUP. To examine the placenta from a transabdominal approach, a 3.5-MHz sector transducer is used most frequently. A 5-MHz linear transducer can be used for transabdominal evaluation; however, depth penetration can limit evaluation of the areas such as the placenta. All four quadrants of the placenta should be examined; right cranial, right caudal, left cranial, and left caudal. Measurements of the CTUP can be made with this technique if the fetus is not in close apposition with the uterine wall. Mares with normal pregnancies should have a minimum combined thickness of the uterus and the placenta (CTUP) of 7.1 ± 1.6 mm, and a maximal CTUP of 11.5 ± 2.4 mm.[230] Pregnancies with an increased CTUP have been associated with the delivery of abnormal foals.[230]

Fig. 43-8 Transrectal imaging of the combined thickness of the uterus and the placenta (CTUP). Measurements of the CTUP (distance between + and +) were recorded from the ventral part of the uterine body, close to the cervix. *a*, Placenta adjacent to the cervix; *b*, allantoic fluid; *c*, amniotic fluid; *d*, the amnion. Modified from Renaudin CD, Troedsson MH, Gillis CL, et al: Ultrasonographic evaluation of the equine placenta by transrectal and transabdominal approach in the normal pregnant mare, *Theriogenology*, 47:559, 1997.

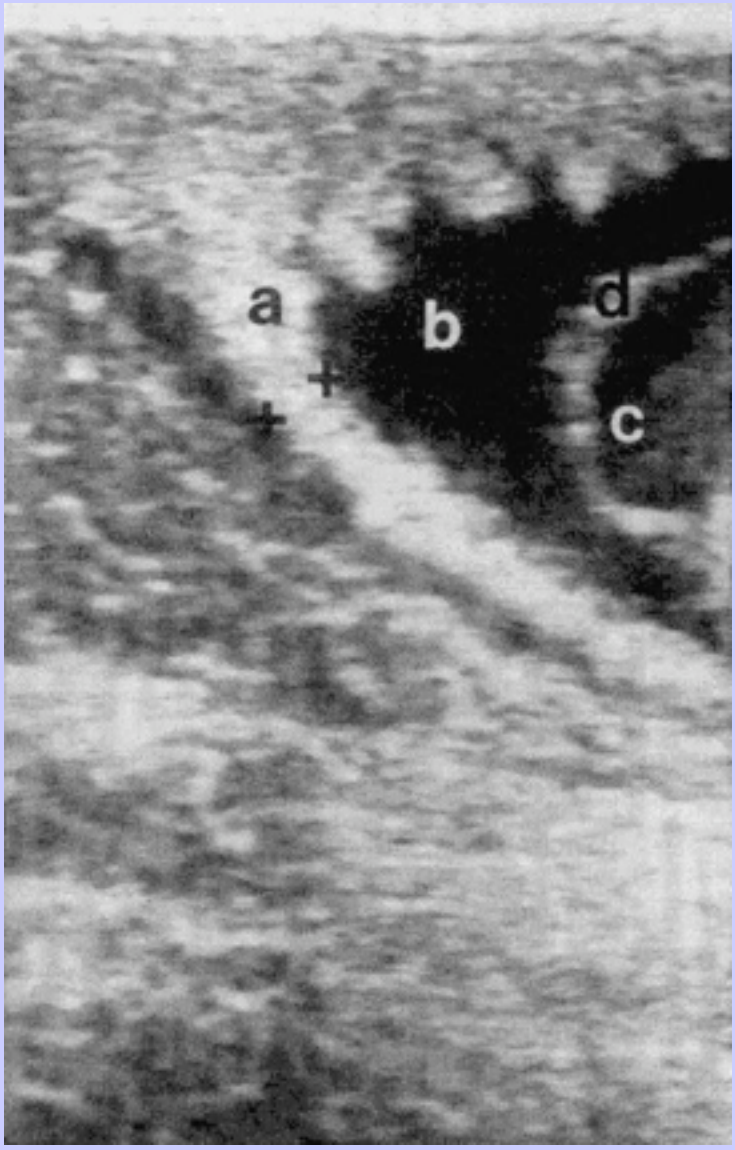

Fig. 43-9 Monthly recordings of transrectal ultrasonographic measurements of the combined thickness of the uterus and the placenta (CTUP) in normal mares from 4 months of gestation and throughout the pregnancy. Month 4 is 91 to 120 days; month 5 is 121 to 150 days; month 6 is 151 to 180 days; month 7 is 181 to 210 days; month 8 is 211 to 240 days; month 9 is 241 to 270 days; month 10 is 271 to 300 days; month 11 is 301 to 330 days; month 12 is 331 to 360 days. Modified from Renaudin CD, Troedsson MH, Gillis CL, et al: Ultrasonographic evaluation of the equine placenta by transrectal and transabdominal approach in the normal pregnant mare, *Theriogenology*, 47:559, 1997.

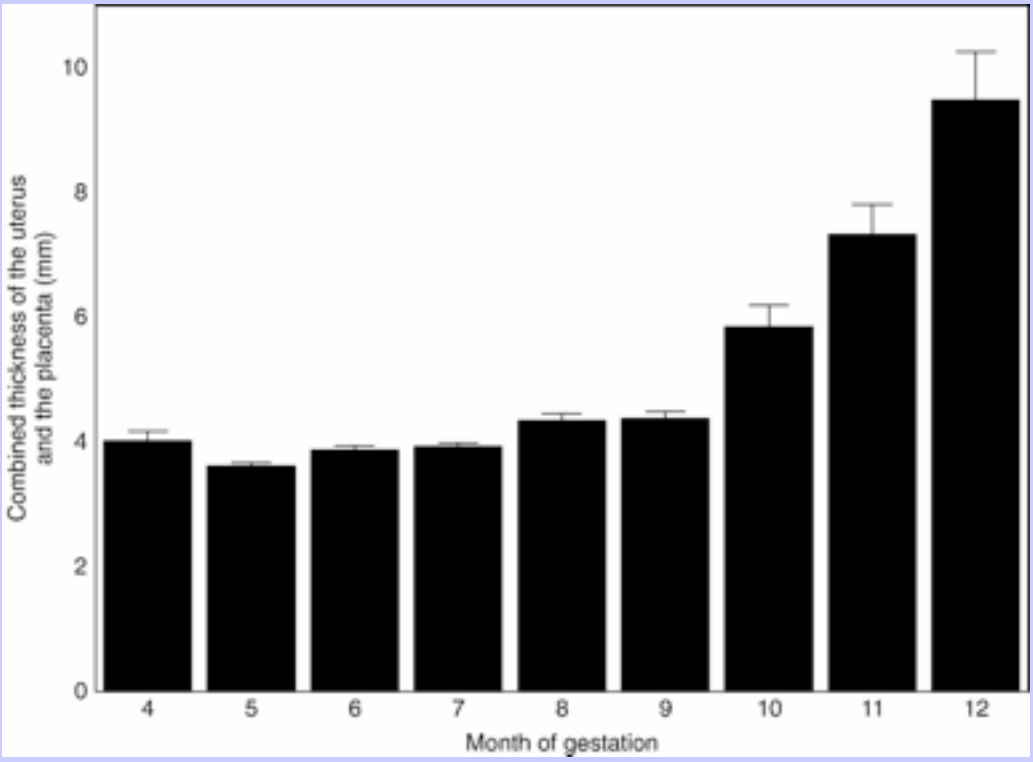
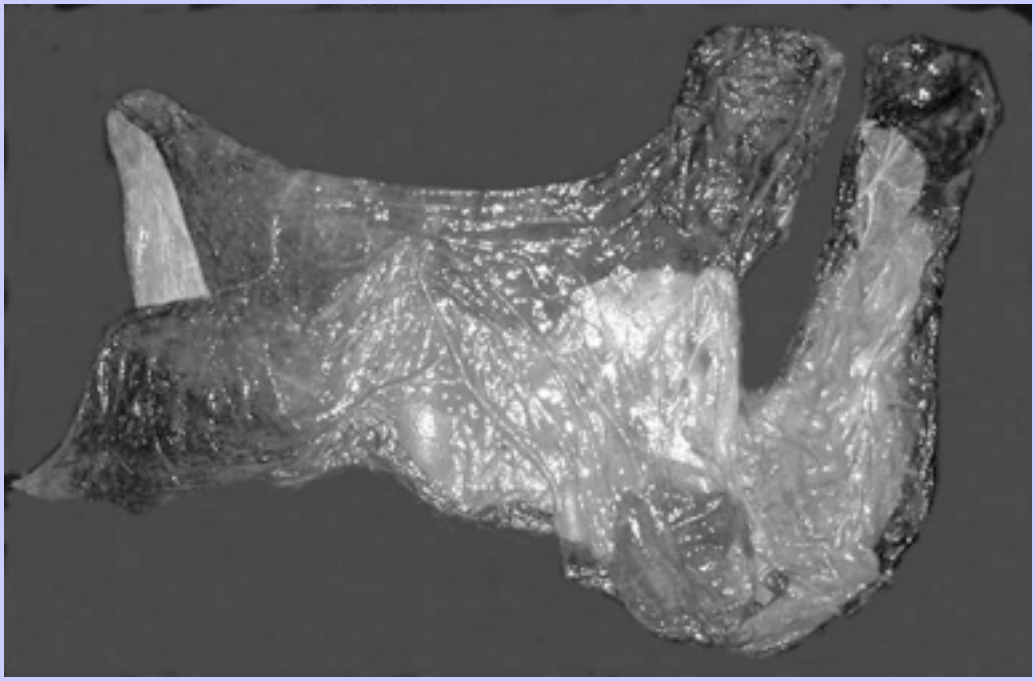


The gross lesions of the fetus are not specific. An increased amount of fluid in the thoracic and abdominal cavities and an enlarged liver are frequently observed in aborted fetuses. Placental lesions are most severe on the chorionic surface at an area from opposite the cervix ("cervical star") to the body of the placenta. The affected area is edematous, thickened, and discolored or brown with a mucoid or fibronecrotic exudate on the surface. The placenta is characteristically thickened and leathery in cases of

mycotic placentitis, with lesions well demarcated from the rest of the chorionic surface. Microorganisms can be isolated from the placenta and several fetal organs, most consistently from the stomach.

Animals with nocardioform placentitis may have premature mammary development but will not have vulvar discharge, owing to the location of the infection. Placental lesions in mares infected with nocardioform actinomycetes are located ventrally in the uterine body and at the base of the uterine horns (Fig. 43-10). Affected areas are avillous, thickened, and covered by thick brown or reddish exudate. Because of the location of the lesions away from the cervical star, transabdominal ultrasonography is needed to diagnose the condition in pregnant mares. Differential diagnoses for this clinical presentation include twins and *Cellulosimicrobium cellulans*, placentitis.[221]

Fig. 43-10 Placenta from a mare with nocardioform placentitis. The characteristic lesions are located ventrally in the uterine body and base of the uterine horns.



Prevalence of fungal abortions varies greatly with region. The most common route of fungal infection is ascending via the cervix, and fungal infections may be seen with a mixed bacterial infection. Abortions are observed from mid to late gestation. Usually no clinical signs in the mare precede the abortion. The chorion generally shows marked evidence of placentitis with edema, thick plaques, and a thick, mucoid exudate. In rare cases, amniotic thickening may be noted. The aborted fetus is often small and emaciated owing to chronic placental insufficiency. Culture of the chorion may be diagnostic but takes time. Culture of the fetus is rarely rewarding. Impression smears of the chorion, and sometimes the fetal stomach, may reveal hyphae.

The equine placenta is part of an endocrine fetal-placental interaction that synthesizes and metabolizes progestagens.[231] This endocrine function of the placenta is important for maintenance of pregnancy

after the endometrial cups and the secondary corpora lutea disappear at approximately day 120 to 150 of gestation. Fetal-placental progesterone is rapidly metabolized to 5α-pregnanes. Mares with placental pathology may have increased plasma concentrations of progestagens as a result of stress to the fetal placental unit.[232,233] Unfortunately, 5α-pregnanes are not readily assayed in a commercial setting, so diagnosis of placental disease using 5α-pregnane concentrations is not possible. There is cross-reactivity between 5α-pregnanes and progesterone using some commercial radioimmunoassays for progesterone. In recent studies[233,234] using an experimental model to induce placentitis, it was found that mares that develop a chronic form of placentitis responded with increased plasma progesterone concentrations. Conversely, mares that developed acute placentitis and abortion soon after infection experienced a rapid drop in plasma progesterone concentrations. It was suggested that measurement of repeated samples of plasma progestin concentrations in mares with placentitis might be a useful method to identify mares that may abort or deliver prematurely.[233] Furthermore, sensitivity of progesterone assays can be improved when they are combined with evidence of placental thickening as detected using transrectal ultrasonography.[234]

43.45.1.2.1.1.1

RELAXIN

Relaxin is produced by the equine placenta and can be detected in peripheral blood plasma from day 80 of gestation and throughout the pregnancy. The role of relaxin during pregnancy is not fully understood, but there is some evidence that placental relaxin production is compromised in mares at risk of aborting their fetuses.[235] There is currently not a commercial test available for equine relaxin.

43.45.1.2.1.2

Treatment and Prognosis

Treatment efforts should be directed at combating infection, reducing inflammation, and controlling myometrial activity. Pregnant mares with clinical signs of placentitis should be treated with systemic broad-spectrum antimicrobials and antiinflammatories. Recent studies have demonstrated that commonly used antibiotics such as penicillin G (22,000 IU/kg q6h), gentamicin (6.6 mg/kg q24h), and trimethoprim-sulfadiazine (30 mg/kg bid) cross the placenta and reach therapeutic concentrations in both placental tissues and the allantoic fluid.[236] Flunixin meglumine (1 mg/kg q12h) and pentoxifylline (8.5 mg/kg bid) have been used to control proinflammatory cytokines associated with placentitis. Treatment with progestins has long been advocated to promote uterine quiescence in mares with uterine pathology. Presumably the antiprostaglandin effect of progestins contributes to reduced myometrial activity by interfering with upregulation of prostaglandin and oxytocin receptors.[237] Without receptor formation, gap junction formation would be inhibited and uterine contractility prevented. Altrenogest at twice the recommended dose (0.088 mg/kg PO q24h) is commonly used.

Work from a large scale clinical trial examined the efficacy of multipronged, long-term therapy for equine placentitis.[238] Investigators examined records of 477 mares over 6 years. Fifteen mares were diagnosed with placentitis. Criteria for treatment included increased thickness of the uteroplacental unit using transrectal ultrasound, placental separation, and/or vulvar discharge and udder development. The average gestational age at diagnosis was 8.6 months. Mares were treated with a combination of systemic antibiotics (trimethoprim-sulfa, ceftiofur, or penicillin and gentimicin), pentoxifylline, altrenogest, and nonsteroidal antiinflammatory agents. Mares were treated until abortion or delivery of a foal. Twelve of 15 treated mares (80%) carried their foals to term, and 11 of 15 (73%) delivered live foals. Birthweights of surviving foals from mares treated for placentitis were similar to those of foals from nonaffected

mares. The benefit of this treatment strategy is supported by recent data from a controlled study on experimentally induced placentitis.[238] Data from these studies suggest that long-term antibiotic, antiinflammatory, and progestin treatment may positively affect pregnancy outcome in mares with placentitis.

Although most mares are capable of conceiving and successfully carrying a foal to term in subsequent breedings, reproductive performance may be negatively affected after ascending and hematogenous placentitis. Treatments for endometritis, such as uterine lavage and intrauterine infusions of appropriate antibiotics, should also be implemented after abortion. Most mares affected by nocardioform placentitis do not require subsequent treatment and show no signs of infertility the following breeding season.

43.45.1.2.2

Equine Herpesvirus 1 Abortion

The most prevalent viral cause of equine pregnancy loss is EHV-1, which causes abortion, paresis, and neonatal foal death. EHV-4 causes abortion in rare cases. The primary route of transmission of EHV-I is via the respiratory tract. The virus invades the respiratory epithelium and establishes a leukocyte-associated viremia. EHV-1 establishes a chronic, possibly lifelong, latent infection. During the initial infection, placental endothelial cells are infected by the virus and transiently present targets to the immune system as the cells present viral particles. The virus eventually inactivates the major histocompatibility complex 1 (MHC-1) ability of the cells to present viral particles, thus evading the immune system.[239] After respiratory infection, EHV-1 causes an episode of viremia and infects the fetus via transplacental migration of virus-bearing leukocytes. Respiratory clinical signs in infected mares may be subclinical. The time between infection and abortion varies greatly from less than 2 weeks to several months.[240] Abortion occurs as a result of a rapid separation of the placenta, causing suffocation of the fetus.[241] Near-term fetuses may be born alive but will die within days. Aborting mares clear the virus quickly from the reproductive tract, and subsequent fertility is often not affected by the disease. Clinical signs and fetal lesions of abortion caused by EHV-1 and those caused by EHV-4 are indistinguishable from each other.[240]

As with all herpesviruses, EHV-1 establishes a latent infection that may recrudesce after stressful events, such as weaning, translocation, introduction of a new animal, or other illnesses. It is unclear whether or not a reactivation event will cause an abortion, but this is considered likely.[242] Recrudescent infections are certainly transmissible. Aborted, infected fetal materials are also highly contagious. Both of these sources may be responsible for abortion epizootics. Although epidemic abortions occur, losses may be confined to only a few mares in a herd.

43.45.1.2.2.1

Clinical Signs and Diagnosis

The primary lesion of EHV-1 is necrotizing vasculitis and thrombosis resulting from lytic infection of the capillary endothelium. The fetus may become infected or remain uninfected, depending on whether or not the virus crosses the uteroplacental barrier. If transplacental fetal infection occurs late in gestation, a live, infected foal may be born but will not usually survive. Stage of pregnancy during which abortions may occur varies, but the vasculitis is most pronounced from the fifth to ninth months of gestation, and 95% of abortions occur in the last trimester of pregnancy.[243]

Abortions occur suddenly without maternal clinical signs. The aborted fetus is fresh with minimal signs of autolysis. Increased fluid in the thoracic and abdominal cavities; congestion and edema of the lungs;

an enlarged liver with small (approximately 1 mm) necrotic, yellow-white lesions; subcutaneous edema; and icterus are commonly found gross lesions in the fetus. Samples for histopathologic diagnosis should be submitted in Bouin's solution. Histologically, the most characteristic lesion consists of areas of necrosis in lymphoid tissue, liver, adrenal cortex, and the lung, with large intranuclear eosinophilic inclusion bodies. In addition, a hyperplastic necrotizing bronchiolitis is often found. Lymphoid tissues are most commonly affected (nodes, thymus, spleen, and Peyer's patches). Other histopathologic lesions may include mild, multifocal, necrotizing lesions in the liver and adrenal cortex and a hyperplastic, necrotizing bronchiolitis. The placenta may be grossly normal or edematous with no specific microscopic lesions.

Available diagnostic methods include serologic tests, virus isolation, and polymerase chain reaction (PCR). Serologic tests are not considered reliable in EHV-1 diagnosis, and virus isolation remains valuable as a method that allows classification and comparative evaluations. Laboratory diagnostics include fluorescent antibody (FA) staining of fetal tissue, virus isolation from aborted fetuses, virus isolation from maternal whole blood, presence of viral inclusion bodies in liver, lung, and thymus, and fetal serology. Equine fetuses have been found to be capable of producing antibodies to EHV-1 at 200 days of gestation. Maternal serology is of limited diagnostic value because mares may abort several weeks after infection. The rise in serologic titer may have disappeared by the time of the abortion.

43.45.1.2.2.2

Treatment and Prognosis

Studies offer conflicting results as to the efficacy of vaccinations in reducing viremia and abortions. Many studies do suggest a beneficial effect of vaccination, and the current recommendation is to vaccinate during the fifth, seventh, and ninth months of gestation.[239,243] Both killed and modified live vaccines are available. The vaccines are not fully protective, and abortion may occur in vaccinated mares. However, consistent vaccination of pregnant mares should be expected to decrease the incidence of abortion storms and sporadic abortions in a herd.

For the effectiveness of a vaccination program to be maximized, it needs to be combined with a management strategy that minimizes exposure of mares to the virus and prevents activation of a latent viral infection. All horses, young, adult, nonpregnant, and pregnant, should be vaccinated to restrict shedding of the virus. Unnecessary stress such as transportation and overcrowding should be avoided. Pregnant mares should be kept separate from other horses on the farm. Newly arrived horses should be isolated from the resident population for 3 weeks, during which time they should be monitored daily for signs of respiratory disease.

After abortion, the fetus and fetal membranes should be transported away from the area without contaminating the surrounding environment. The stall in which the mare aborted should be disinfected with a phenolic or iodinophoric compound, and the bedding should be prevented from contaminating other areas on the farm. All pregnant mares on an infected farm should remain on the farm until they have foaled. No horse should leave the farm until 3 to 4 weeks after the last abortion.

43.45.1.2.3

Equine Viral Arteritis

Equine viral arteritis (EVA) is caused by equine arteritis virus (EAV). The primary target of EAV is the vasculature. Shortly after infection EAV can be found in the macrophages and later in the lymph nodes. The virus infects circulating monocytes and becomes systemic in distribution by 3 days after the primary infection, resulting in a carrier state (important in stallions). In about a week's time after the primary

infection EAV infects the blood vessel endothelium and causes enough damage by 10 days after the primary infection to cause abortion. Abortion is likely due to the effects of myometritis and vasculitis. Serum progesterone concentrations (produced exclusively by the placenta in the last half of equine pregnancy) fall to baseline levels before the abortion, because of placental hypoxia. The virus is also present in the renal tubular epithelium and is shed in the urine.[244]

EVA is caused by a pestivirus. Infection is often inapparent, and abortion is an occasional occurrence in infected animals.[245] Although the pathophysiology is not well established, fetal death may occur by fetal anoxia secondary to compression of myometrial vessels by edema and decreased progesterone production by the placenta.[246]

43.45.1.2.3.1

History and Clinical Signs

Clinical signs may be absent or highly variable and may include pyrexia, depression, anorexia, leukopenia, limb edema, stiffness of gait, rhinorrhea and epiphora, conjunctivitis, rhinitis, urticarial rash, localized or diffuse edema, and abortion. Abortion typically occurs at 5 to 10 months of gestation and follows the onset of clinical signs by several days but up to 2 months. Less frequently, severe respiratory distress, ataxia, mucosal papular eruptions, submaxillary lymphadenopathy, and intermandibular and shoulder edema may be observed.[244] Infection is rarely fatal in adults but is more frequently fatal in neonates. The virus may be transmitted in the semen, and infected stallions may serve as long-term carriers. Clinical pathologic findings are variable, inconsistent, and nonspecific and include hypoxia, hypercapnia, respiratory or metabolic acidosis, lymphocytosis or lymphopenia, neutrophilia or neutropenia, thrombocytopenia, and hyperfibrinogenemia. Gross and histologic lesions differ in severity with the virulence of the particular viral strain. Edema, congestion, and hemorrhage of the subcutaneous and lymphoid tissues and viscera are the most common gross lesions. Histologic lesions may be found in the vasculature, lymphoid tissues, lungs, intestines, adrenal glands, kidneys, and skin.[244] Abortion may occur without any clinical signs in the mare, and the fetus may be fresh or autolyzed. Fetal lesions are uncommon.

43.45.1.2.3.2

Laboratory Diagnosis

Diagnosis is by serologic testing in conjunction with complement-dependent virus neutralization. There are no characteristic features of EVA infection in the fetus, although autolysis and myocardial arteritis have been reported. EAV is readily isolated or detected by PCR techniques in fetal tissues and the placenta.

43.45.1.2.3.3

Epidemiology and Control

Transmission may occur venereally from infected stallions to mares. Reproductive performance of venereally infected mares is not affected, but contact transmission from venereally infected mares to late gestational mares may cause abortion. Outbreaks were reported in 1953, 1984, and 2006 in the United States. With the exception of these incidents, occasional outbreaks have occurred, with abortion occurring at low incidence.[245] Mares may be isolated after infection but usually do not become carriers. A proportion of naturally infected stallions become persistently infected with EAV and shed the virus constantly in semen. Incidence of seropositive animals is higher in standardbreds than in thoroughbreds, and regulatory guidelines may govern the use of seropositive thoroughbred stallions. Carrier stallions

1455 1456

may be the reservoir for the disease between outbreaks and should be isolated and bred only to immune mares. Mares bred in this way should be isolated for 3 weeks. A modified live vaccine is available for mares and stallions. Control involves vaccination of seronegative stallions under the guidance of regulatory authorities. There is some evidence that prepubertal infection of colts does not result in permanent carrier status.

43.45.1.2.4

Equine Infectious Anemia Abortion

Equine infectious anemia (EIA) is a retroviral infection transmitted by horseflies.[247] After systemic infection with EIA, mares abort during the febrile stage of infection and may abort at any stage of gestation. Foals from infected but asymptomatic mares and stallions are seronegative (precolostral) and clinically normal at birth. Mechanism of abortion is unknown but may be secondary to systemic illness because EIA virus is not found in amniotic fluid.[247] Coggins' test will confirm seropositive status but is not a definitive diagnosis for abortion.

43.45.1.2.5

Leptospirosis Abortion

Leptospirosis causes a number of bacterial abortions in some areas and was reported to be responsible for 2.2% of abortions in a Kentucky study.[210] The serovar responsible shows regional variability. Serovar *Leptospira*, Pomona has most commonly been associated with leptospirosis abortion in mares, but *Leptospira*, Grippotyphosa, *Leptospira*, Hardjo, *Leptospira*, Bratislava, and *Leptospira*, Icterohemorrhagiae have also been isolated from sporadic abortions.[248] Infected animals shed the spirochete in their urine, which contaminates groundwater and serves as a source for further infections. Many horses are seropositive for leptospires but are subclinical.

43.45.1.2.5.1

Clinical Signs and Diagnosis

Clinical signs may include pyrexia, hemoglobinuria, jaundice, and abortion. Aborted chorioallantoic lesions are similar to those of other bacterial placentitis cases (nodular cystic allantoic masses, edema, necrotic areas of chorion, and necrotic mucoid exudate coating the chorion) but may show a diffuse pattern of distribution, indicating a hematogenous source of placental infection. Funisitis has been reported in leptospira cases of abortion, and examination, both gross and histologic, of the umbilical cord should always be a part of every abortion investigation.[249] Serologic antibody conversion lasts for years, and so serologic diagnoses are not very helpful. Gross lesions are nonspecific. Diagnosis is best done by FA tests or Warthin-Starry silver stain (WS) staining of the allantochorion and umbilical cord. Demonstration of leptospirosis could aid in rapid diagnosis and have important clinical and therapeutic indications in the case of live-born, weak foals.[249]

43.45.1.2.5.2

Treatment and Control

Horses may shed spirochetes in urine for up to 90 days; therefore affected animals should be isolated and treated with antibiotics. Aborting mares should be isolated, and the stalls should be disinfected. Infected mares may be treated with streptomycin (10 mg/kg twice daily), penicillin (10 to 15,000 IU/kg twice daily), or oxytetracycline (5 to 10 mg/kg) for a period of 1 week. Because *Leptospira*, Pomona is

the most common isolate in the United States, mares should be separated from other leptospiral hosts such as ruminants and pigs. Vaccines for cattle are not effective in horses.

43.45.1.2.6

Protozoal Abortion

Pregnant mares with equine monocytic ehrlichiosis (Potomac horse fever), caused by the protozoa *Neorickettsia risticii*, may abort. Abortions caused by *N. risticii*, have been documented in both natural and experimental cases.[250,251] Mares were infected at 90 to 180 days of gestation and aborted at around 217 days of gestation.

43.45.1.2.6.1

Clinical Signs and Diagnosis

Abortions have been observed 2 to 3 months after clinical signs of ehrlichiosis.[252] Abortions were associated with placentitis and RFMs. Fetal histologic lesions include enterocolitis, periportal hepatitis, myocarditis, and lymphoid hyperplasia with necrosis of the mesenteric lymph nodes and spleen. Recovery of the protozoan may be from fetal bone marrow, spleen, lymph node, colon, or liver.[250,251] The diagnosis can be confirmed by identifying a small number of rickettsiae by PCR assay.

43.45.1.2.6.2

Treatment and Prevention

Treatment with oxytetracycline (6.6 mg/kg IV once daily) for 5 days in pregnant mares with clinical signs of ehrlichial colitis may prevent or reduce the incidence of abortion. Commercial vaccines against equine ehrlichiosis are available, but the protective effect of vaccines against abortion is unknown.

Neospora caninum, is a known protozoal abortifacient in cattle. This protozoan has not been definitively shown to cause abortion in the mare, but its presence has been documented in aborted foals, suggesting the need for further investigation.[253]

43.45.1.2.7

Insect-Related Abortion

In the equine breeding season of 2001, central Kentucky horses experienced pregnancy losses estimated to have affected more than 3000 mares (>60% of mares on some farms[254]) and to have resulted in over $330 million in losses.[255] The syndrome was named *mare reproductive loss syndrome*, (MRLS). On a much smaller scale, MRLS was documented in mare abortions in north central Florida during the 2006 breeding season. Epidemiologic studies noted abnormal weather patterns (sudden freezing in mid April followed by unusually warm springtime temperatures) and positive correlations with the presence of black cherry trees *(Prunus serotina)*, and abnormally large numbers of the eastern tent caterpillar *(Malacosoma americanum)*.,[256] Pregnancy loss was later linked to ingestion of the caterpillars themselves, with the toxic agent related to the larval exoskeleton.

43.45.1.2.7.1

Clinical Signs and Diagnosis

Clinical signs preceding abortion and failure to maintain pregnancy are typically not observed. Both early (40 to 150 days' gestation) and late (near term) pregnancies are affected. Hyperechoic amniotic and allantoic fluids can be noted on ultrasonographic examination, along with a dead or dying fetus

(slow heart rate, <75 beats/min), which would then be expelled within several days.[257,258] Characteristic histologic lesions are noted in the placenta and umbilical cord. In many cases, endometrial cultures are positive for non—beta-hemolytic streptococci and actinobacilli. *Actinobacillus*, species identified in cases of MRLS are identical to commensal organisms found in the oral cavities and alimentary tracts of healthy horses.[259] Larval hairs (cetae) are hypothesized to migrate through gastrointestinal system and translocate commensal organisms from the oral cavity and intestines to other sites.[256]

1456

1457

43.45.1.2.7.2

Treatment and Prevention

Because clinical signs are absent in the mare before fetal death, treatment is not possible. Prevention is aimed at limiting exposure to *M. americanum*, larvae. Applying insecticides, physically removing caterpillar nests from trees, removing black cherry trees, muzzling mares in pasture, and supplementing hay feeding in pastures to minimize grazing have all been used.

43.45.1.2.8

Salmonella, Abortion

Salmonella, Abortus equi *(Salmonella abortivoequina*, or "contagious abortion") was a common cause of abortion in the early 1900s but is now rare. Non—host-specific species, including *Salmonella*, Typhimurium, now cause most equine salmonella abortions. Abortion caused by *Salmonella*, is discussed under abortions in ruminants.

43.45.1.2.9

Trypanosomiasis (Dourine)

The protozoan parasite *Trypanosoma equiperdum*, causes a venereally transmitted genital infection that may be followed by fatal systemic dissemination in horses. Systemic illness may cause abortion. It occurs in tropical and subtropical regions and has been eradicated from North America.[11] Dourine is diagnosed by isolation of trypanosomes in uterine discharge. Exposed animals can be detected by serology (complement fixation). Control strategies require identification and treatment or slaughter of infected animals.

43.45.1.2.10

Abortion Caused by Endotoxemia

Gram-negative septicemia and endotoxemia associated with intestinal disorders that alter the integrity of the mucosal barrier (e.g., intestinal obstructions, acute enteritis, colitis, grain overload) result in the release of vasoactive metabolites including PGF. Endogenous release of PGF during an episode of experimental endotoxemia has been shown to cause luteolysis and abortion during the first 2 months of pregnancy in mares.[260] The equine pregnancy is dependent on ovarian sources of progesterone for the first 80 days of gestation. After this time the fetoplacental unit takes over progesterone production, which is necessary for maintenance of the pregnancy.

43.45.1.2.10.1

Clinical Signs and Diagnosis

Abortions follow a recent episode of stress induced by endotoxemic shock or gram-negative endotoxemia. Pregnancy loss at early stages of gestation may go undetected unless fetal membranes or

parts are found in the stall. Abortions during later stages of the pregnancy may be observed as vaginal discharge or the detection of an expelled fetus.

43.45.1.2.10.2 Treatment and Prevention

Daily administration of a progestagen (Altrenogest 0.044 mg/kg PO) has been shown to effectively prevent experimental endotoxin-induced abortion.[260] If the animal is treated while the pregnancy is still CL dependent (approximately <day 80), analysis of serum progesterone concentrations after the acute episode of the disease helps in deciding if the supplementation needs to continue. Serum progesterone concentrations of less than 1 ng/mL indicate the loss of an active CL, and supplemental progestagen treatment should continue until the fetoplacental unit is known to be capable of maintaining the pregnancy. For practical reasons supplementation until day 100 is commonly recommended. Serum progesterone concentrations greater than 1 ng/mL are compatible with a functional CL, and the progestagen treatment can gradually be discontinued. Treatments with flunixin meglumine or other prostaglandin inhibitors have not been proven to effectively prevent endotoxin-induced fetal losses unless the agents are administered before clinical signs appear.

43.45.2 RUMINANTS

Information on the major causes of abortion in cows, sheep, and goats is summarized in Tables 43-8 and 43-9.

In large commercial operations a low percentage of intermittently occurring abortions is considered acceptable; such abortions are seen as “background abortions.” In beef and dairy operations 2% to 3% and 10% are considered acceptable, respectively. Abortion levels beyond these are considered abnormal and are usually investigated. Only rarely is a cause established. When investigating bovine abortions, it is important to determine commonalities among abortion events including stage of pregnancy affected, sire used, heifers versus cows affected, dates of new arrivals to the herd, season of year, vaccination protocols, presence of dogs, and management practices among different groups. Cows and heifers on the farm presumed to be pregnant should be evaluated to detect unobserved pregnancy losses. These examinations should document apparently normal, open animals who had previously been documented as pregnant, those with mummified fetuses, and those with pyometra. If possible an entire fetus (or more than one) should be submitted for culture, serology, and histopathology. If the placenta is available, this should be submitted as well. If it is not practical to submit the entire animal and placenta, tissues including lung, stomach and contents, liver, spleen, and placenta should be collected and appropriately submitted for culture (chilled), viral isolation (frozen), and histopathology (formalin fixed).

43.45.2.1 NONINFECTIOUS CAUSES

Noninfectious causes of abortion in ruminants include the following:

- Heat stress
- Other stress
- Nitrate toxicity
- Malnutrition (rare)

- Pine needle toxicity
- Drug induced (corticosteroids)
- Physical

43.45.2.2 INFECTIOUS CAUSES

43.45.2.2.1 Bovine Herpesvirus 1

Bovine herpesvirus 1 causes IPV and IBR. The latter disease is the major cause of bovine viral abortion. IBR manifests as upper respiratory disease and abortion. The virus causes clinical signs in both dam and fetus. Immune dams exposed to the virus do not experience abortions. In naive animals the virus is carried in leukocytes and can become localized in placental tissues. Fetuses exposed to the virus usually die within 24 hours of placental infiltration. Although other stages of pregnancy may be affected, 5 to 6 months' gestation is the most susceptible stage. Fetal lesions include renal hemorrhagic edema; acute general necrosis in the liver, spleen, kidneys, lungs, and adrenal glands; widespread hemorrhage; petechia; epithelial destruction; and hepatic necrosis with intranuclear inclusion bodies. The amnion may be thickened without obvious signs of inflammation.

Diagnosis of IBR is by virus isolation from the placenta, identification of intranuclear inclusion bodies in fetal tissues, or serum neutralization testing. If the latter is to be used, at least two samples must be taken days apart. The first must be negative and the second positive, or the first must be positive and the second titer must show a fourfold increase. Serum testing may not be helpful because the dam may have been infected months before the abortion and the titer after the abortion may actually be falling.

Table 43-8 Major Causes of Bovine Abortion

Cause and Common Names	Usual Stage of Gestation	Major Fetal Lesions	Diagnostic Tests
Bovid herpesvirus 1, IBR	Fifth to ninth months	Multifocal necrosis with intranuclear inclusions (liver, lung, spleen, kidney)	Histopathology, virus isolation, FA test of frozen fetal kidney
Bluetongue (orbivirus)	Any stage	Anomalies of skeletal and nervous systems	Pathology, virus isolation, fetal serology
BVD virus, pestivirus	Any stage	Anomalies of skeletal, nervous, cardiovascular, respiratory, or other systems	Pathology, FA test on fetal tissues, fetal serology (virus neutralization, ELISA), serologic survey in herd
EBA, foothill abortion, spirochete?	Third trimester	Lymphadenopathy, splenomegaly, hepatopathy	Pathology
Brucella abortus, brucellosis, Bang's disease	Third trimester	Placentitis, fibrinous serositis, bronchopneumonia	Culture, maternal serology (card test, plate, or tube agglutination)
Campylobacter fetus, subsp. *venerealis*, campylobacteriosis, vibriosis	Usually early embryonic death	Placentitis, fibrinous serositis, bronchopneumonia, hepatitis	Pathology, darkfield examination, culture
Haemophilus somnus,	Any stage	Placentitis	Histopathology, culture
Leptospira interrogans, leptospirosis	Fifth to ninth months	Icterus, edema, renal degeneration and inflammation	Fetal and maternal serology
Leptospira interrogans, listeriosis	Eighth or ninth month	Placentitis	Histopathology, culture
Salmonella, Dublin, *Salmonella*, Typhimurium	Third trimester	Placentitis	Culture
Aspergillus fumigatus, and all fungal species, mycotic abortion	Third trimester	Placentitis, bronchopneumonia, dermatitis	Histopathology, fungal culture
Sarcocystis cruzi,	Third trimester	Protozoa in caruncles	Histopathology or FA of caruncles
Tritrichomonas foetus, trichomoniasis	First half	Placentitis, bronchopneumonia	Microscopic demonstration of organism, culture

Bovine neosporosis	Mid gestation	Similar to those found in toxoplasma-aborted sheep fetuses	Histopathology, seroepidemiology

BVD, Bovine virus diarrhea; *EBA*, epizootic bovine abortion; *ELISA*, enzyme-linked immunosorbent assay; *FA*, fluorescent antibody; *IBR*, infectious bovine rhinotracheitis.

Table 43-9 Major Causes of Abortion in Sheep and Goats

Cause and Common Names	Usual Stage of Gestation	Major Fetal Lesions	Diagnostic Tests
Bluetongue, orbivirus	Any stage	Anomalies of skeletal or nervous systems	Pathology, IFA, serology
Border disease, pestivirus, hairy shaker disease	Any stage	Dysplasia of skeleton, CNS, and fleece	Pathology, virus isolation, serology (cross-reacts with BVD)
Coxiella burnetii, Q fever	Near term	Necrotizing placentitis	Histopathology, microscopic demonstration of rickettsiae, complement fixation, ELISA
Chlamydia psittaci, EAE	Fourth or fifth month	Necrotizing placentitis	Histopathology, microscopic demonstration of organism, fluorescent antibody on fetal tissues or cultures, paired sera
Campylobacter fetus, subsp. *fetus*, vibriosis	Last 6 weeks	Placentitis, serositis, multifocal hepatic necrosis	Pathology, microscopic demonstration of organism, culture
Toxoplasma gondii, toxoplasmosis	Any stage	Necrosis and calcification in cotyledons	Pathology, demonstration of organism, serology (e.g., agglutination, ELISA)

BVD, Bovine virus diarrhea; *CNS*, central nervous system; *EAE*, enzootic abortion of ewes; *ELISA*, enzyme-linked immunosorbent assay; *IFA*, immunofluorescent antibody.

Prevention of disease is by vaccination (though infection and latency may occur despite vaccination). It is recommended to vaccinate heifers at 6 months and administer a booster 3 to 4 weeks before breeding. A modified live virus is commonly used but is unsafe in pregnant cows from the third to eighth months of gestation. A killed viral vaccine is available for pregnant cow use; a modified live virus vaccine labeled for intranasal administration is also available.[261]

43.45.2.2.2

Bovine Virus Diarrhea Virus

Bovine virus diarrhea virus (BVDV) is a pestivirus that can produce early embryonic death, fetal anomalies, or abortion (see Chapter 32 for complete discussion). Isolates from bovine aborted fetuses are usually noncytopathic.[262]

43.45.2.2.2.1

History and Clinical Signs

Although fetal death is most common during the first trimester, abortion can occur at any stage of gestation.[263,264] Pathogenicity of the disease depends on gestational time of infection, the viral strain, viral biotype (cytopathic or noncytopathic), and fetal immunocompetence.[265] Often there is a history of repeat breeding and a recent episode of febrile disease in the herd before the onset of abortions.[266]

43.45.2.2.2.2

Laboratory Diagnosis

Fetal loss generally occurs 10 to 27 days postexposure, with expulsion of the fetus up to 50 days later.[265] As a result the fetus is most often autolyzed, although in some cases it may be mummified or fresh. The aborted fetus may have a variety of dysplastic lesions, including cerebellar hypoplasia, cerebral malformations (hydrencephaly, porencephaly, microencephaly) and cataracts, brachygnathia, arthrogryposis, alopecia, thymic hypoplasia, and intrauterine growth restriction.[5,263,266,267] Microscopic lesions include a mild nonsuppurative placentitis. Nonsuppurative vasculitis may be observed in the placenta, liver, or lymph nodes.[266]

Virus isolation from fetal tissue is seldom successful, likely because of the protracted time before fetal expulsion generally occurs after infection. Viral antigen may be detected by FA test on kidney, lung, or lymph node.[266] Virus neutralization and enzyme-linked immunosorbent assay are used to detect antibodies in fetal thoracic fluid, which indicate prenatal exposure to the virus but do not necessarily incriminate BVDV as the cause of abortion. Maternal titers are seldom of diagnostic value because a rise in titer generally occurs before abortion.[5]

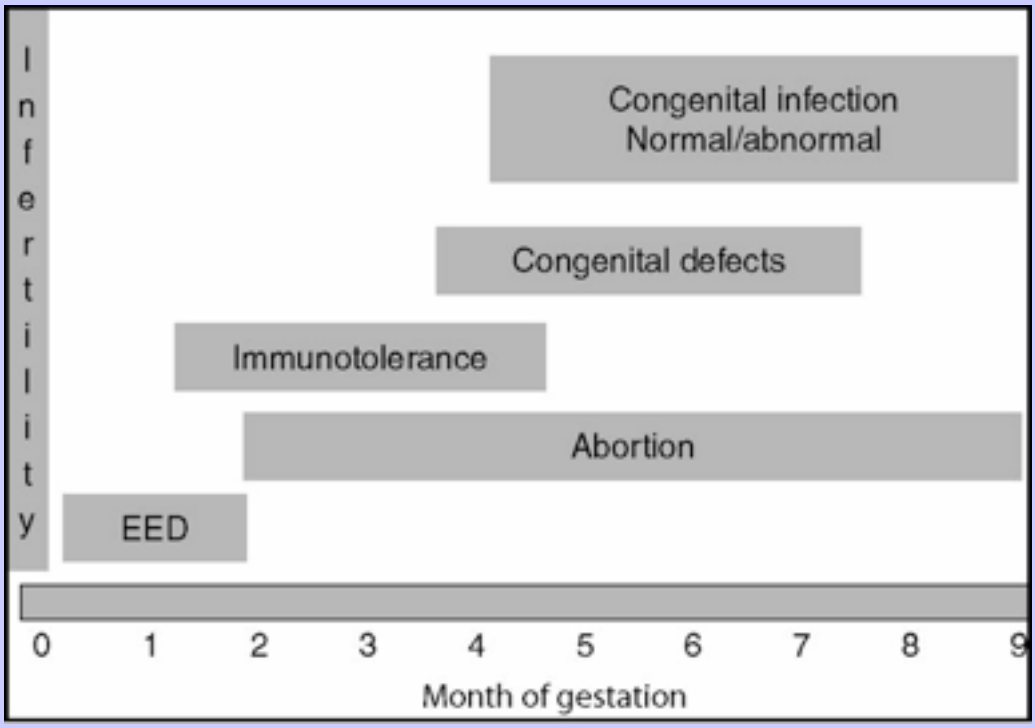
43.45.2.2.2.3

Pathophysiology

BVDV may be shed in most body secretions. The effects of exposure to BVDV vary greatly depending on the gestational time during which exposure occurred (Fig. 43-11). In seronegative cows, exposure to BVDV at the time of breeding prevents conception.[268] Placental attachment at approximately 35 days' gestation seemingly must precede fetal infection. During the first 4 months of gestation, infection usually causes fetal death and abortion.[166] Fetuses that survive infection with noncytopathic strains between 18 and 125 days' gestation will be persistently infected (PI), are typically seronegative at birth, and subsequently shed BVDV continuously.[265] They may develop mucosal disease later in life from superinfection with cytopathic BVD virus.[269,270] Fetuses infected at between 100 and 150 days' gestation, considered congenitally infected (CI), are at risk for the development of dysplastic lesions including teratologic defects in the brain, skin, or bronchioles. Fetuses infected after 150 days usually recover without dysplastic lesions.[263] Recent evidence, however, suggests that those fetuses born with

neutralizing titers to BVDV are more likely to develop a serious illness within the first 10 months of life and less likely to conceive as heifers than those calves born without neutralizing titers to BVDV.[271,272]

Fig. 43-11 Potential clinical reproductive outcomes after infection with bovine virus diarrhea virus. *EED*, Early embryonic death.[265]



43.45.2.2.2.4 Epidemiology

Most cattle have serum antibodies to the virus. The abortion rate may approach 25% with new infection of a susceptible herd.[5]

43.45.2.2.2.5 Control

BVDV is not fully controlled with vaccination. Herd health plans must focus on elimination of PI animals and prevention of new PI animals being introduced into the herd.

43.45.2.2.3 Leptospirosis

Leptospirosis is a spectrum of diseases caused by multiple serovars of *Leptospira interrogans. Leptospira*, Hardjo is the major serovar associated with bovine leptospiral abortion, although isolations of *Leptospira*, Pomona*, Leptospira*, Canicola, *Leptospira*, Icterohemorrhagiae, *Leptospira*, Grippotyphosa, and *Leptospira*, Szwajizak have also been reported.[5,266] Two serologically indistinguishable but genetically distinct types of serovar Hardjo have been identified: *L. interrogans*, serovar Hardjo (type hardjo-prajitno)

and *Leptospira borgpetersenii*, serovar Hardjo (type hardjo-bovis). Serovar Hardjo type hardjo-bovis is cosmopolitan in cattle populations, whereas type hardjo-prajitno is isolated primarily from cattle in the United Kingdom.[265]

43.45.2.2.3.1

History and Clinical Signs

In cattle, *Leptospira*, Hardjo is associated with infertility, early embryonic death, abortions from 4 months' gestation to term, and birth of weak calves. Abortion rate is usually less than 10% but may approach 50% in some areas.[273] *Leptospira*, Pomona abortion usually occurs in the last 3 months of gestation, with an abortion rate as high as 50%.[5] Clinical signs of leptospirosis in the cow may include icterus, hemoglobinuria, anemia, fever, and mastitis that is characterized by a flaccid udder and thick ropy secretions from all four quarters, but usually cows abort without clinical illness.[266] Dead or weak calves may be delivered at term.[273] Abortions caused by serovar Hardjo tend to occur sporadically rather than in storms (as may be seen with serovars Pomona or Grippotyphosa).

1459 1460

43.45.2.2.3.2

Laboratory Diagnosis

The aborted fetus is usually autolyzed, icteric, and edematous. Histologically, renal tubular necrosis is accompanied by lymphocytic interstitial nephritis, pneumonia, and placentitis.[5,266]

Leptospires are rapidly destroyed by autolysis or freezing. Isolation from fetal liver, kidney, or brain is possible but slow and impractical. Leptospires may be isolated or demonstrated by darkfield microscopy, FA staining, or histologic techniques in fetal or placental tissues or in the urine of the aborting dam within approximately 2 weeks after abortion.[5,266]

Diagnosis is usually based on serology. A few infected fetuses develop microagglutination titers of 1:10 or more. It is difficult to distinguish among vaccinated, acutely infected, and recovered animals, but titers to *Leptospira*, Pomona greater than 1:12,800 in the dam suggest leptospiral abortion. Maternal titer usually has peaked by the time of abortion. Single titers of 1:800 or more in unvaccinated animals, seroconversion, or fourfold changes in titers in paired sera indicate leptospirosis in the herd. Titers to *Leptospira*, Hardjo are often less than 1:100 in affected cows and seldom exceed 1:1600.[266]

43.45.2.2.3.3

Pathophysiology

Hematogenously spread leptospires colonize the gravid uterus up to 142 days after infection. Abortion occurs 1 to 6 weeks after acute disease with *Leptospira*, Pomona infection and 1 to 3 months with *Leptospira*, Hardjo.[5] *Leptospira*, Hardjo remains in the oviducts of infected cows up to 22 days after calving.[273]

43.45.2.2.3.4

Epidemiology

Leptospira, organisms are ubiquitous and an important cause of abortion in all cattle-producing regions. *Leptospira*, organisms persist in the genital tract and kidneys. The organisms localized in the kidneys of infected animals are shed in the urine and serve as a source of infection for other animals. The organisms localized in the female reproductive tract are responsible for abortions. Aborted tissues are

infectious to other animals and humans and should be handled with caution.[274] Vaccination may be useful in endemic areas.

43.45.2.2.3.5

Treatment and Control

In abortion outbreaks, pregnant cows can be vaccinated with killed bacterin and treated with oxytetracycline (antibiotic treatment can be limited to sick cows in dairy herds).[275] Aborting cows should be isolated and treated with streptomycin if they are not destined for slaughter. Aborted fetuses and placentas should be removed from the premises.[276] Preventing exposure to swine, rodents, and contaminated water lessens the opportunities for infection.[5,202] *Leptospira*, Pomona usually has no permanent effect on fertility, but infection with *Leptospira*, Hardjo has been associated with persistent herd infection and recurring abortions.[5]

Herd vaccination is recommended at 6-month intervals or more frequently in areas with heavy exposure to leptospires. Vaccination programs are aimed at reducing urinary shedding of leptospires and decreasing fetal loss. However, a commercial pentavalent leptospiral vaccine (serovar *Leptospira*, Hardjo type hardjo-prajitno is used for the *Leptospira*, Hardjo component of U.S. Department of Agriculture [USDA]—licensed leptospiral vaccines) did not prevent renal colonization, urinary shedding, or fetal infection after conjunctival instillation of cows with serovar *Leptospira*, Hardjo type hardjo-bovis (the only type of *Leptospira*, Hardjo isolated from cattle in the United States).[277]

43.45.2.2.4

Epizootic Bovine Abortion (Foothill Abortion)

Epizootic bovine abortion (EBA) or foothill abortion is a syndrome of late abortions in cattle in the foothills bordering the central valley of California.[278] Once thought to be caused by *C. psittaci*, studies have demonstrated that EBA differs from chlamydial abortion.[278] Currently a spirochete-like agent isolated from abortuses and from the tick vector of EBA is under investigation as the causative agent.[279–281]

43.45.2.2.4.1

History and Clinical Signs

Late abortion or delivery of weak calves occurs in affected herds. Many fetuses in the sixth to seventh month of gestation may be aborted, especially from heifers without premunition immunity from natural exposure to the causative agent. Older native cows show no clinical signs of infection.

43.45.2.2.4.2

Laboratory Diagnosis

A 3-month period is required for full development of pathologic changes in the fetus. Superficial cervical lymph nodes are enlarged up to 16 g, the spleen is enlarged up to 250 g, the thymus is slightly smaller than normal, and the liver may be enlarged and nodular.[266,278,280] Histologically there is loss of thymic cortical lymphocytes; remaining lymphocytes are enlarged and poorly differentiated. Follicular hyperplasia, histiocytosis, vasculitis, necrosis, and pyogranulomas occur in lymph nodes and spleen. Lymphohistiocytic proliferation may also occur around vessels in the liver, lung, and meninges.[266]

EBA has been diagnosed mainly by pathologic examination of the fetus. Recent studies have demonstrated high levels of IgG (3 mg/mL or more) in fetal blood.[266,278] A spirochete-like agent can be demonstrated in the plasma of aborted fetuses but also may occur in plasma of normal fetuses.[279] Currently no serologic test for EBA exists because the cause is uncertain.

43.45.2.2.4.3

Pathophysiology

Infection is transmitted by the soft-shell tick *Ornithodoros coriaceus*.,[280,281] The disease also can be transmitted with fresh or frozen fetal tissue.[278] Transformation and proliferation of fetal lymphocytes and macrophages occur by 50 days but are not severe enough for diagnosis until 100 days after maternal exposure to the tick vector. IgG and IgM are deposited in vascular lesions, but increase in fetal serum immunoglobulin is not detectable until at least 80 days after tick exposure.[278,281] Repeated superinfection may be necessary to result in fetal death.[280] Because at least 90 days are required for development of fetal lesions, infection after 6 months' gestation is not likely to result in abortion.[5,266]

43.45.2.2.4.4

Epidemiology

EBA is limited to the range of the tick vector in the foothills bordering the central valley of California.[278] Of the annual calf loss in California, 5% to 10% is attributed to EBA.[281] The prevalence of infection by the spirochete is far greater than the prevalence of abortion.[280] Abortion occurs 3 to 4 months after exposure to ticks but almost always late in gestation, regardless of the time of tick exposure.[282] Older native cows from enzootic areas usually do not abort, and introduced cows and heifers generally abort only once.[278] The abortion rate may be 30% to 80% in susceptible animals.[266,282]

1460

1461

43.45.2.2.4.5

Treatment and Control

Chlortetracycline therapy (2 to 5 g/day in the feed) reduces the rate of abortion.[281] Currently no vaccine exists for EBA, but abortions can be controlled by exposing heifers to the tick vector before breeding or by changing from spring to fall calving,[5] which takes advantage of limiting exposure to the last trimester of gestation in some management systems. Therefore exposure of susceptible pregnant cattle to the tick only after the sixth month of pregnancy is a practical solution for ranchers using summer foothill pastures and fall calving. The tick lives in ground duff (e.g., leaves) and is not found on cattle that graze in irrigated pastures and most other areas outside of brushy foothills.

43.45.2.2.5

Brucella abortus, Abortion

B. abortus, infection (Bang's disease) causes abortion in cattle and, less commonly, in sheep and goats. Horses may be infected with *B. abortus*, which has been associated with fistulous withers, but usually experience no infertility, abortion, or other clinical evidence of infection. Bovine infections are caused by eight biovars of *B. abortus*, three of which (biovars 1, 2, and 4) are recognized in the United States.[5]

43.45.2.2.5.1

History and Clinical Signs

Abortion is the chief clinical sign of bovine brucellosis and usually occurs after the fifth month of gestation. Lameness, mastitis, epididymitis, and/or orchitis may be present in infected herds.[283]

43.45.2.2.5.2

Laboratory Diagnosis

Autolysis frequently obscures gross lesions in the fetus, but fibrinous serositis may be apparent, and abomasal content may be discolored and flocculent. Placentitis is a consistent finding. Cotyledons are necrotic; the intercotyledonary placenta is thickened and opaque with accumulation of odorless, flocculent, yellow-brown exudate between maternal and fetal membranes. Histologically there is suppurative placentitis (and endometritis in the dam). Suppurative bronchopneumonia and lymphoreticular hyperplasia are frequent histologic findings in the fetus.

Diagnosis depends on culture of *B. abortus*, from fetal lung, abomasum, or placenta or from maternal uterine or mammary secretions. Organisms and *Brucella*, antigen can be detected in fetal tissues by avidin-biotin-peroxidase complex immunostaining.[284]

No serologic test is 100% accurate, but a positive card test or titer of 1:100 or more on plate or tube agglutination suggests brucellosis. False-negative serologic reactions occur in approximately 15% of infected cows, particularly just before or after parturition. False-positive reactions are a problem in cows vaccinated with strain 19. Supplemental tests such as the Rivanol test, complement fixation, and mercaptoethanol sensitivity of agglutination are used in suspect cases. Dairy herds are surveyed by the *Brucella*, ring test on milk.[5] In goats, tube agglutination titers of 1:25 or more indicate infection.[283]

43.45.2.2.5.3

Pathophysiology

Initial replication of *B. abortus*, occurs in regional lymph nodes. Bacteremia is followed by colonization of supramammary lymph nodes, the mammary gland, and the gravid uterus. Uterine infection occurs during the second trimester.[5,285] In the placenta the bacteria appear first in phagosomes of erythrophagocytic trophoblasts. Replication occurs in the rough endoplasmic reticulum of chorioallantoic trophoblasts.[285] Preferential replication in chorioallantoic trophoblasts has been attributed to their erythritol content; however, the placentas of several laboratory rodents that lack detectable erythritol still support *B. abortus*, replication.[286] The organism also occurs in fetal placental endothelial cells and capillary lumina, where it is associated with vasculitis and destruction of chorionic villi. Placental inflammation spreads along the allantochorion to involve additional cotyledons with resultant chorioallantoic ulceration, necrosis of trophoblasts, and ulcerative endometritis. Fetal death results from placental disruption and endotoxemia.[5,285] The fetus is frequently retained 1 to 3 days in utero. Numerous bacteria are expelled from the genital tract at parturition, but shedding usually stops by 3 weeks after abortion.[5]

43.45.2.2.5.4

Epidemiology

Infection with *B. abortus*, occurs naturally by ingestion. Contaminated materials are infectious for humans and should be handled with caution. Infection is not easily transmitted between cattle separated by fences or roads.[287] Most calves infected at birth clear the infection, but persistent congenital infection has been documented.[288,289]

Bovine brucellosis has been nearly eradicated in the United States by test and slaughter of seropositive cattle and vaccination. However, a reservoir remains in bison and elk, especially in the greater Yellowstone area.

43.45.2.2.5.5

Treatment and Control

Treatment of brucellosis is usually not effective. Combination therapy with long-acting oxytetracycline and streptomycin has been shown to reduce shedding in most cows and potentially eliminate infection in some,[290] but because of the eradication program used in many countries, infected cows are rarely treated. In the United States, infected individuals are destroyed, and exposed herdmates are quarantined to the herd until slaughter or the herd is recertified as brucellosis-free (United States Department of Agriculture, 2003).

In the past, strain 19 vaccine was used as part of the eradication program. However, vaccinated and field strain—infected cattle could not be differentiated. A newer vaccine for *B. abortus*, vaccine strain RB51, was developed to overcome the serologic problems associated with the strain 19 vaccine.[291] Animals vaccinated with RB51 lack antibodies to the O-polysaccharide chain and can thus be distinguished from field-infected cattle. Strain RB51 is also less abortifacient for cattle than strain 19, although vaccination of pregnant heifers may result in abortion and subsequent zoonotic exposure if obstetric assistance is necessary (Centers for Disease Control, Morbidity and Mortality Weekly Report, March 13, 1998), and so the vaccine is to be administered only to young heifers before pregnancy.[261,290a,291]

43.45.2.2.6

Campylobacter fetus, subspecies *venerealis*, Abortion

C. fetus, subsp. *venerealis*, is the main cause of bovine campylobacteriosis (vibriosis).[5] The organism is an obligate parasite of the bovine genital tract and is not known to cause disease in other species.[266]

43.45.2.2.6.1

History and Clinical Signs

Infection with *C. fetus*, subsp. *venerealis*, mainly causes temporary infertility or early embryonic death, but sporadic abortions from the fourth to eighth months of gestation are possible.[266] The usual history includes a high percentage of cows exposed for the first time returning to estrus or found nonpregnant after the breeding season, and cows calving late because they returned to estrus one or more times.

1461

1462

43.45.2.2.6.2

Laboratory Diagnosis

Autolysis is usually minimal, and the lungs of the term fetus may be partially inflated. Dehydration, fibrinous serositis, and necrotizing placentitis may be apparent grossly. Histologically, bronchopneumonia and hepatitis may also be evident. Diagnosis is based on demonstration or isolation of the organism. By darkfield microscopy the bacterium appears as a curved rod with darting corkscrew motility.[266] Cows that abort may have serum antibody titers; however, they may not be diagnostic because they are not specific for *C. fetus*, subsp. *venerealis*., Culture from placenta or fetal abomasal contents requires at least 72 hours. The vaginal mucus agglutination test is used to survey herds for infection.[5] Alternatively the penis and preputial mucosa of infected bulls may be swabbed and cultured, although culture is difficult because the organism is slow-growing and often overwhelmed by saprophytes.

43.45.2.2.6.3

Pathophysiology

Within a week of vaginal infection the organism is established in the uterus, causing mucopurulent endometritis, which persists 3 to 4 months. Intrauterine infection either prevents conception or causes embryonic death, and infected heifers typically return to estrus by 40 days. Less commonly, abortions occur at up to 8 months' gestation.[5,266]

43.45.2.2.6.4

Epidemiology

C. fetus, subsp. *venerealis*, is ubiquitous. Venereal transmission from infected bulls to virgin heifers approaches 100%. Cows with previous exposure to infected bulls develop immunity and therefore are less likely to experience infertility than heifers. The abortion rate seldom exceeds 10%.[266]

43.45.2.2.6.5

Treatment and Control

Infected cows usually recover spontaneously within 5 months and resist reinfection. Recovery is hastened by intrauterine infusions of streptomycin and penicillin. Infertility may be permanent if endometritis or salpingitis is severe.[5] Heifers should be vaccinated with a killed bacterin before breeding. Most vaccines are administered 1 month before breeding and require a booster vaccination 2 weeks later.[*,†] Higher than normal doses of vaccine may be needed to clear the infection from bulls. Cows and bulls must be vaccinated annually. Exclusive use of *C. fetus*, subsp. *venerealis*,—negative semen via AI controls the disease by preventing transmission.

* Vibrin, SmithKline Beecham Animal Health, Exton, PA.

† Trivib-5L, Fort Dodge Labs, Fort Dodge, IA.

43.45.2.2.7

Haemophilus somnus, Abortion

H. somnus, has been associated with vulvitis, vaginitis, endometritis, weak calf syndrome, stillbirths, and occasional abortion in cattle.

43.45.2.2.7.1

Laboratory Diagnosis

Aborted fetuses have been free of gross lesions. Necrotizing placentitis is associated with fibrinoid necrosis of placental arteries.[207] Diagnosis is based on recovery of large numbers of the organisms in relatively pure culture from placenta or fetus, histologic evidence of placentitis, and lack of other apparent causes.

Interpretation of maternal titers to *H. somnus*, is difficult, and it is best to take paired serum samples. Titers between 1:256 and 1:512 in nonvaccinated herds may be the result of early active or chronic infection. Titers between 1:1040 and 1:4096 indicate recent active infection. A fourfold change in titer in paired sera is the best indicator of active infection.

43.45.2.2.7.2

Pathophysiology

Although *H. somnus*, can be isolated from the genital tract of clinically normal cows,[194] the rate of isolation is higher in cows with endometritis or cervicitis.[207,292] Experimentally, *H. somnus*, can adhere to zona pellucida—intact embryos and cause degeneration.[293] Vaginitis can be induced by inoculation with *H. somnus*,[294] and abortion has been induced by intraamniotic, intravenous, or intrabronchial challenge with the organism.[295] Cervical infusion with the organism has resulted in colonization of the chorioallantois and placentitis, but calves were born alive without culturable *H. somnus*.,[296,297]

43.45.2.2.7.3

Treatment and Control

Antibiotic treatment and vaccination anecdotally increase fertility in herds affected with *H. somnus*,—induced vulvovaginitis.[207]

43.45.2.2.8

Listeria monocytogenes, Abortion

Listeriosis is caused by *L. monocytogenes*., Listerial abortions are of importance mainly in ruminants.

43.45.2.2.8.1

History and Clinical Signs

Bovine abortions usually occur in the last 2 months of gestation.[266] Infected ewes and does typically abort in the last month.[5,298] Fever, depression, RFMs, or endometritis may occur,[5,266,299] but often the dam shows no clinical signs of infection.

43.45.2.2.8.2

Laboratory Diagnosis

In less severely autolyzed fetuses, fibrinous polyserositis may be apparent. Most aborted fetuses have gray-white hepatic foci up to 2 mm in diameter. Similar foci may be visible in cotyledons; exudation occurs between cotyledons. Abomasal erosions have been reported in aborted lambs.[266] Histologically, suppurative placentitis and endometritis are consistent findings.

Listeria, is readily cultured from abortuses without cold enrichment. Serovars 1 and 4b are commonly isolated from bovine fetuses; serovars 4b and 5 are the usual ovine isolates.[266] *Listeria*, appears in impression smears as gram-positive pleomorphic coccobacilli.[266]

43.45.2.2.8.3

Pathophysiology

Listerial abortion can be induced experimentally in cattle 6 to 8 days after infection and in sheep 3 to 11 days after infection. Fetuses die from placentitis and septicemia and are often retained in utero several days before expulsion.[266]

43.45.2.2.8.4

Epidemiology

Listerial abortion is usually sporadic, and incidence seldom exceeds 15%.[266] Infection is most common in the winter and has been associated with feeding of silage. The elevated pH of spoiled silage enhances multiplication of the organism. Aborted tissues are infectious for humans and should be handled with care.

43.45.2.2.8.5

Treatment and Control

The effect on fertility is usually transient, and aborting animals tend to resist reinfection. Tetracycline may be used in remaining pregnant animals in the herd.[5] Aborting animals should be segregated, and fetuses and placentas should be removed from the premises. The feeding of spoiled silage should be avoided.

1462

1463

43.45.2.2.9

Mycoplasma, Abortion

Mycoplasmal isolations from the bovine genital tract have been mainly *M. bovigenitalium*, and *Mycoplasma bovis. M. bovis*, is probably the more important cause of abortion.[299] *Mycoplasma mycoides*, subsp. *mycoides*, (see *Mycoplasma*, Polyarthritis) and *Mycoplasma agalactiae*, have been associated with caprine abortions.[5]

43.45.2.2.9.1

History and Clinical Signs

M. bovigenitalium, is associated with granular vulvovaginitis and less commonly with endometritis, especially in heifers. Infertility is more common than abortion. *M. bovis*, causes mastitis and abortion.[299] In goats, mycoplasmal infection is associated with septicemia, arthritis, pneumonia, mastitis, and abortion.[5]

43.45.2.2.9.2

Laboratory Diagnosis

Placentitis and fetal pneumonia have been associated with bovine mycoplasmal abortion.[299] Isolation of *Mycoplasma*, from the genital tract, milk, placenta, or fetus indicates infection. However,

mycoplasmosis should not be considered the cause of abortion unless placentitis or fetal inflammation is present and other more likely causes of abortion have been eliminated.

43.45.2.2.9.3 Pathophysiology

M. bovigenitalium, can be isolated from the vagina of as many as 12% of clinically normal cows, but *M. bovis*, is isolated from fewer than 1%. Vulvitis can be induced by inoculation with mucosal scarification with *M. bovigenitalium;*, therefore venereal transmission may be the natural route of infection.[5,299] Experimental inoculation with *M. bovis*, induces abortion with placentitis and fetal pneumonia.[299,300] *M. bovigenitalium*, is rarely isolated from abortuses or normal fetuses.[5]

43.45.2.2.9.4 Epidemiology

Mycoplasma, species are ubiquitous, but mycoplasmal abortions are not commonly documented.

43.45.2.2.9.5 Treatment and Control

Tetracycline or tylosin is the recommended antibiotic for mycoplasmal granular vulvovaginitis in heifers.[299]

43.45.2.2.10 *Salmonella*, Abortion

A variety of *Salmonella*, serotypes have been isolated from aborted fetuses of cattle, sheep, goats, and horses. A complete discussion of salmonellosis is presented elsewhere. Infection is acquired by ingestion of contaminated feed or water. Maternal septicemia is followed by localization of salmonellae in tissues, including the pregnant uterus, where placentitis and fetal septicemia occur. Salmonellosis accompanied by endotoxemia causes early pregnancy loss without colonization of the uterus, because the infection and endotoxemia cause endogenous prostaglandin release. Endogenous $PGF_{2\alpha}$ initiates luteolysis and abortion in the first trimester (<100 days for cattle), as is the case with exogenous administration of PGF products.

43.45.2.2.10.1 History and Clinical Signs

The animal may show systemic signs before abortion. Abortion may occur at any stage of gestation and is characterized by placental necrosis, edema, and hemorrhage. RFMs and fetal autolysis may occur. Abortion may be accompanied by diarrhea, fever, or vaginal discharge, particularly in the ewe, but often infection is not clinically apparent in the dam.[266,301,302] Fetuses also may be lost as a result of stillbirth or perinatal septicemia.

43.45.2.2.10.2 Laboratory Diagnosis

The fetus is frequently autolyzed. Placentitis is usually present. Diagnosis is based on isolation of the organism and evidence of placentitis or inflammation of fetal tissues. FA techniques can identify the bacteria in impression smears or sections of placenta or fetal tissue.[266] The dam can be tested

serologically for evidence of recent active infection,[301] but at present many diagnostic laboratories do not perform *Salmonella*, serology.

43.45.2.2.10.3

Pathophysiology

Infected adult animals are often short-term carriers and shed salmonellae in the feces or milk. True long-term asymptomatic carriers occur mainly with the host-adapted serotypes: *Salmonella*, Dublin in cattle, *Salmonella*, Abortus ovis in sheep, and *S. abortivoequina*, (or *Salmonella*, Abortus equi) in horses. Salmonellosis caused by *Salmonella*, Abortus equi has been eradicated in the United States. Occasionally, long-term carriers of other serotypes are seen; these are usually intestinal carriers and fecal shedders. Infection usually occurs by ingestion. There is no evidence of venereal transmission.[301] Maternal septicemia is followed by localization of the organism in a variety of tissues, including the pregnant uterus. The bacteria multiply in and cause necrosis of connective tissues of the cotyledon.[301] The incubation period between infection and abortion varies from approximately 1 week to 1 month.[5,302] Fetal death results from placentitis and fetal septicemia.[266,303] In most cases, maternal shedding of the organism in cattle ceases by 5 weeks after calving.[301]

In a second mechanism of *Salmonella*,-induced abortion, *Salmonella*, septicemia causes endotoxemia and release of endogenous PGF, which causes luteolysis and abortion. In this case the fetus and placenta are culture negative for salmonellae.

43.45.2.2.10.4

Epidemiology

Bovine abortion resulting from salmonellosis is caused mainly by *Salmonella*, Dublin and *Salmonella*, Typhimurium. Abortion is sporadic and most common in the summer and fall.[301]

Ovine abortion is associated with *Salmonella*, Typhimurium*, S.*, Dublin, *Salmonella*, Arizona, and *Salmonella*, Abortus ovis. *Salmonella*, Abortus ovis (which infects only sheep) is enzootic in parts of England and Europe but is not reported from the United States.[5,266] Young ewes in late gestation are most susceptible, and the abortion rate may approach 50%,[5,302] but usually only one or two ewes in a flock abort.[266]

43.45.2.2.10.5

Treatment and Control

Metritis is a rare complication of salmonellosis that can be fatal.[266] Usually there is no lasting effect on fertility, but animals infected with host-adapted serotypes may become carriers and should be cultured and tested serologically and culled if positive. Salmonellosis can be controlled by hygiene and by avoiding the introduction of carrier animals. Aborting animals should be isolated; the fetus, placenta, and contaminated material should be removed from the premises. *Salmonella*, species are infectious for humans; therefore aborted tissues should be handled with caution.

43.45.2.2.11

Ureaplasma, Abortion

Ureaplasma, is a small bacterium without cell walls; it differs from *Mycoplasma*, in its ability to hydrolyze urea. *U. diversum*, has been associated with granular vulvitis and abortion in cattle.

43.45.2.2.11.1

History and Clinical Signs

Granular vulvitis appears as reddish nodules in the vulvar mucosa, with mucopurulent discharge in the early stages. The discharge is usually more copious and protracted than with IPV induced by herpesvirus.[5,299] Affected cows are not systemically ill.[266] The organism has been recovered from embryo flushing media and can adhere to the zona pellucida, resisting removal by washing. It is believed to be responsible for an 18% reduction in pregnancy rate in embryo recipients when the transfer medium contains the organism.

43.45.2.2.11.2

Laboratory Diagnosis

Gross lesions include thickening of placental membranes with foci of hemorrhage and fibrinous exudate. Gross lesions are seldom apparent in the fetus. Microscopically the placenta is fibrotic, with heavy mononuclear cell infiltration, multifocal necrosis, fibrin deposition, and mineralization. Cuffs of lymphocytes surround fetal intrapulmonary airways.[266] Diagnosis is based on isolation of the organism from genital mucosa, placenta, or fetal stomach or lung and the presence of genital or fetal inflammation.

43.45.2.2.11.3

Pathophysiology

Ureaplasma, can be isolated from the genital tract of normal cows and from normal fetuses.[304] Vulvitis has been induced by inoculation of virgin heifers with *U. diversum*.,[304] Uterine involvement is considered rare but may cause conception failure, early embryonic death, or abortion. Abortion presumably results from placentitis.[5] Intraamniotic inoculation of *U. diversum*, caused placentitis, abortion, and fetal alveolitis in two of four experimental cows.[304] One cow delivered a weak calf at term. Experimental infection in ewes did not decrease fertility.[305]

43.45.2.2.11.4

Epidemiology

Bovine infection is common, but documented abortions caused by *Ureaplasma*, are rare.[299] Infertility is more common in heifers than in cows.

43.45.2.2.11.5

Treatment and Control

Nonirritating tetracyclines by intrauterine infusion are recommended for treatment. Products may not be approved for intrauterine use.[5] Uterine contamination can be avoided by use of the double-rod technique of AI.[5]

43.45.2.3

MISCELLANEOUS BACTERIAL ABORTIONS

In addition to the aforementioned bacteria, other bacteria occasionally produce maternal septicemia. Many of these bacteria are ubiquitous, frequently contaminate aborted fetuses and placentas, and should not be considered the cause of abortion unless (1) they are isolated from the placenta and fetus in large numbers and

relatively pure culture, (2) placentitis or fetal inflammation is evident, and (3) other more likely causes of abortion have been eliminated.[266]

In cows, most bacterial infections of the uterus result from septicemia. Miscellaneous bacterial causes of infertility and abortion include *A. pyogenes, E. coli, Bacillus*, species, *Pasteurella*, species, *Staphylococcus*, species, *Streptococcus*, species, *F. necrophorum*, and *Bacteroides melaninogenicus*.,[266]

A. pyogenes, with or without accompanying anaerobes has been associated with pyometra and abortion in cattle.[188,266,306] Abortions are sporadic and may occur at any stage of gestation. Clinical signs are seldom apparent in the cow. The fetus is commonly autolyzed, and placentitis is typical. Polyserositis may be evident. In fetuses aborted in the first half of gestation, 1-mm yellow foci (bacterial colonies) may be grossly apparent in the lung.[266]

In the ewe or doe, miscellaneous bacterial causes of abortion include Staphylococcus aureus, Streptococcus species, Pasteurella species, E. coli, Yersinia pseudotuberculosis, Francisella tularensis, Histophilus ovis, Bacillus species, *A. pyogenes*, and Corynebacterium species.[266,307–310]

A spirillum-like organism has been documented as a cause of ovine abortion, fetal mummification, stillbirth, and birth of weak lambs. Abortion generally occurs in the last 2 weeks of gestation. Placentitis is consistently present; many fetuses also have fibrinous peritonitis and focal hepatic necrosis that resembles that of campylobacteriosis.[311] Abortion can be reproduced experimentally by inoculation of pregnant ewes.[312] Diagnosis is based on pathologic lesions and identification of the spindloid flagellated organism by darkfield microscopy of fetal abomasal content or liver or by anaerobic culture on selective medium.[311,313]

43.45.2.3.1

Tritrichomonas foetus

Trichomoniasis is a venereal infection of cattle caused by the flagellated protozoan *T. foetus*., [5,189,266,314,315]

43.45.2.3.1.1

History and Clinical Signs

Infertility characterized by a high percentage of cows returning to estrus or found nonpregnant after the breeding season and cows calving late plus occasional pyometras and abortions are the most common clinical signs of trichomoniasis. Pyometra in postcoital heifers or cows suggests that trichomoniasis may be the cause. Abortions generally occur in the first half of gestation at a rate of 5% to 30%.[314] The placenta may be expelled or retained.[5,266]

43.45.2.3.1.2

Laboratory Diagnosis

Diagnosis in the female is made by identifying or culturing trichomonads from cervicovaginal mucus (approximately 76% sensitivity), uterine exudate, placental fluids, or fetal abomasal contents. [5,189,266,314,315] Preputial smegma collected from bulls by using a plastic pipette run against the mucosa can also be cultured for trichomonads (sensitivity 80% to 90%). Diamond's medium (or modified Pastridge medium) is recommended for cultures from cows, bulls, or aborted fetuses.[315] Samples should be transported at ambient temperature, kept out of sunlight, not refrigerated, and delivered promptly to the diagnostic laboratory. The organisms are identified microscopically by their size (10 μm×15 μm),

the presence of three anterior flagellae and an undulating membrane, and a characteristic jerky, rolling motion.[266]

There are no specific gross lesions in aborted fetuses. However, placentitis is a consistent microscopic lesion, and trichomonads can frequently be recognized in the placental stroma in histologic sections. Organisms may also be observed in the fetal lung in association with pyogranulomatous bronchopneumonia.[316]

43.45.2.3.1.3

Pathophysiology

Trichomoniasis is transmitted venereally from infected bulls to cows or vice versa. The organisms colonize the vagina, cervix, uterus, and oviducts; yet they do not generally interfere with conception. Embryonic death frequently occurs within the first 2 months of infection,[5] followed by a 2- to 6-month period of immunity to reinfection.[189] Clearance of infection in cows commonly occurs within 95 days; infection rarely persists as long as 6 months.[314] However, infection in bulls over 4 years of age is permanent and the main source of carryover from one breeding season to the next in beef cattle.[189]

1464

1465

43.45.2.3.1.4

Treatment and Control

Systemic treatment of infected animals with imidazole compounds (ipronidazole, dimetridazole) is effective, but these compounds are prohibited in food animals in the United States.[242,317,318] Infected cows should be either culled or given at least 3 months' sexual rest. The use of AI with semen from *T. foetus*,—negative bulls controls the disease once infected natural service bulls have been removed from the herd. In natural breeding situations, vaccination, use of young virgin bulls, and testing and elimination of positive bulls older than 3 years of age will allow herd owners to gain control over the incidence of trichomoniasis.

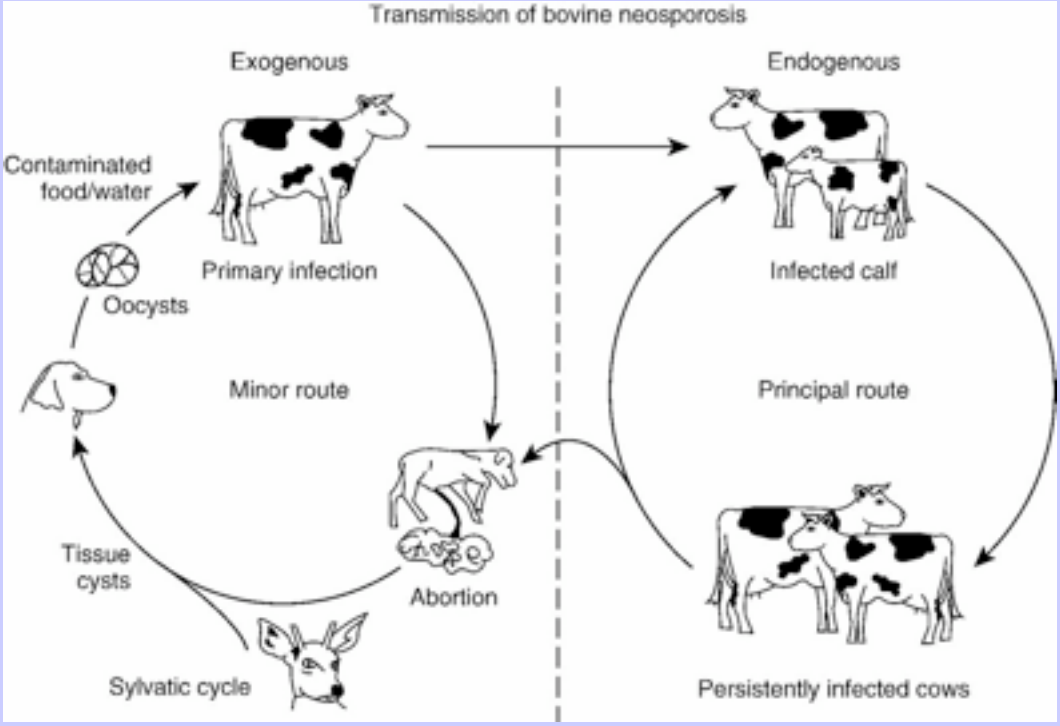
43.45.2.3.2

Neospora caninum, Abortion

Abortion in cattle caused by *N. caninum*, is relatively common and of economic importance especially in dairy cattle. Congenital infection with limb paresis or dysfunction at birth as a result of encephalomyelitis may also occur. Canids are the definitive hosts and shed oocysts in their feces after ingestion of infected tissues from intermediate hosts (Fig. 43-12). Both the domestic dog and the coyote have been shown to transmit the oocysts in their feces.[319,320,321] Along with cattle, deer have been shown to serve as intermediate hosts.[321] The role of birds and wild rodents as intermediate hosts is suspected but has not yet been definitively demonstrated.[321] Aborted, infected fetal tissues ingested by canids will also result in massive shedding of oocysts in feces.[322] Transmission may be vertical (dam to fetus in utero) or via point-source horizontal transmission (ingestion of feed contaminated with feces containing oocysts).[323,324] Horizontal transmission from cow to cow does not occur. Bovine fetal lesions are distinctive and may include nonsuppurative encephalitis with foci of necrosis and gliosis, nonsuppurative myositis, hepatitis, and, most consistently, myocarditis.[261] Most abortions occur in the early second trimester, but they may occur throughout gestation. Diagnosis is based on characteristic lesions in aborted fetuses, and seroepidemiologic study of an equal number of aborting and nonaborting herdmate cows if the proportion of seropositives is statistically higher in those that have aborted.[325] Finding one aborting cow to be

seropositive does not confirm *N. caninum*, as the cause, and cows that abort once because of *N. caninum*, are not protected from future abortion caused by this organism. A vaccine based on whole killed tachyzoites (Neoguard1, Intervet, Millsboro, Del.) is available for *N. caninum*.

Fig. 43-12 Transmission of bovine neosporosis. Oocysts are produced by the canine definitive host, and their subsequent ingestion by a susceptible pregnant cow leads to infection of the fetus (exogenous transplacental transmission). Liveborn infected heifer calves would be expected to remain infected into adulthood, when they, in turn, may pass infection to their fetuses (endogenous transplacental transmission). Spread of *N. caninum*, in this second way is the principal route whereby the parasite is propagated in a herd.



43.45.2.3.3

Sarcocystis, Abortion

Sarcocystosis may cause abortion in cattle, sheep, and goats. Cattle are infected by *Sarcocystis cruzi*, sheep by *Sarcocystis ovicanis*, and goats by *Sarcocystis capracanis*.,

43.45.2.3.3.1

History and Clinical Signs

Most cattle are infected with *Sarcocystis*, but do not show clinical signs of infection; however, massive or repeated infections may elicit depression, anorexia, weight loss, lameness, hair loss, emaciation, or death. Abortions occur in late gestation, usually in severely affected animals.[266,326,327]

43.45.2.3.3.2

Laboratory Diagnosis

There are no specific gross lesions in the aborted fetus. Histologically protozoa may be observed in villi and small arteries of the cotyledon or (more likely) the caruncle but are seldom seen in the bovine, ovine, or caprine fetus. Parasites are more likely to be observed in the fetal brain than in other tissues.[326] Nonsuppurative inflammation may occur in the placenta or, less commonly, in fetal tissues, particularly the brain, heart, lung, liver, or kidney.[266,326,327]

FA demonstration of numerous developing protozoa in the cotyledon or caruncle is considered diagnostic. Caruncles are reported to be atrophied.[326] The protozoa can also be isolated by feeding aborted tissues to canids and recovering coccidian sporocysts from their feces.[266]

1465

1466

43.45.2.3.3.3

Pathophysiology

The pathogenesis of abortion in sarcocystosis is unclear. Generally, numerous spores are required to induce abortion experimentally. Fetal invasion by *Sarcocystis*, is rare, and abortion may result from maternal fever, anemia, or placental insufficiency.[326] Pregnant does apparently have diminished immunity to *Sarcocystis*, because low doses of *S. capracanis*, result in fetal death without maternal illness if given in early pregnancy.[328]

43.45.2.3.3.4

Epidemiology

Ruminants are infected by consumption of canid feces that contain oocysts. *Sarcocystis*, occurs in the skeletal and cardiac muscle of most cows without associated lesions or clinical evidence of illness.

43.45.2.3.3.5

Control

Effective therapeutic regimens for clinically ill animals have not been developed. For the lifecycle of *Sarcocystis*, to be broken, feeds should be kept free of dog or cat feces. These carnivores should not be allowed to eat aborted fetuses, placentas, or other ruminant carcasses.

43.45.2.4

Fungal Abortions

43.45.2.4.1

Mycotic Diseases That Cause Abortion

Fungal causes of bovine abortion include *Aspergillus, Absidia, Mucor, Rhizopus, Candida*, and *Mortierella*.,[266,329,330] Mycotic abortion is uncommon in sheep and goats.[266]

43.45.2.4.1.1

History and Clinical Signs

Mycotic abortions usually occur in the latter half of gestation (often near term) and seldom are associated with prodromal or postabortion clinical signs in the dam.

43.45.2.4.1.2

Laboratory Diagnosis

The most consistent lesion is placentitis with necrosis and thickening of fetal membranes. In ruminants, both cotyledons and the intercotyledonary placenta are affected. Histologically, necrotizing inflammation of the chorionic villi is associated with vasculitis and thrombosis.[266] Gross lesions may not be apparent in the fetus, but granulomatous bronchopneumonia is frequently observed histologically.[266,330–332] In bovine aspergillosis the fetus is often near term with minimum autolysis and partially inflated lungs. Emaciation and dehydration with multifocal dry, scaly skin lesions occur in approximately 25% of affected fetuses.[266] With other fungi the aborted fetus is often autolyzed, placentitis may be more severe, and skin lesions, if present, tend to be moister than those of aspergillosis.[266] The placenta is characteristically thickened and leathery. The fetus may be emaciated, and granulomatous bronchopneumonia has been observed.[331] The fungus can be isolated from the fetus and placenta or demonstrated on histologic sections with immunostaining.

43.45.2.4.1.3

Pathophysiology

The route of fungal infection in the bovine uterus is thought to be hematogenous.[11]

43.45.2.4.1.4

Epidemiology

Mycotic abortion generally affects only one or two animals in a herd and is more common in the winter.[266] Fungi cause 3% to 10% of bovine abortions.[333,334] *Aspergillus*, accounts for up to 80% of bovine mycotic abortions; Mucorales account for an additional 10% to 15%.[5] *Mortierella*, is a common abortifacient in Australia and New Zealand and has been associated with feeding of grass silage,[330,334] but *Mortierella*, abortion is rare in the United States.

43.45.2.4.1.5

Control

The only means of control of mycotic abortion is reduction of exposure to fungal agents.

43.45.2.4.2 DOES AND EWES

43.45.2.4.2.1 INFECTIOUS CAUSES

43.45.2.4.2.1.1 Bluetongue Abortion

Bluetongue is an orbivirus infection that can result in embryonic death, abortion, and fetal anomalies in sheep, cattle, or other ruminants. Twenty-four serotypes of bluetongue virus have been recognized; five of these (serotypes 2, 10, 11, 13, and 17) occur in the United States (see Chapter 32 for complete discussion and Chapter 35 for nervous system anomalies).[335]

43.45.3 Border Disease (Hairy Shaker Disease)

Border disease or hairy shaker disease is an ovine pestivirus infection that causes embryonic and fetal death; stillbirths; dysplasia of the central nervous system, skeleton, and fleece; and birth of weak lambs with low viability.

43.45.4 *Coxiella burnetii*, (Q Fever)

Coxiella burnetii, a rickettsia, is the causative agent of Q fever, which can cause abortions in sheep and goats. Most infections are completely asymptomatic, and the disease is of more importance as a zoonosis than as a cause of ovine or caprine abortion.

43.45.4.1 History and Clinical Signs

Late abortions or delivery of weak lambs may occur in an affected flock over a period of 2 to 4 weeks.[5,302]

43.45.4.2 Laboratory Diagnosis

There are no specific gross lesions in the fetus, but the placenta is thickened with white, chalky plaques and red-brown exudate, especially in intercotyledonary areas. Histologically cotyledonary and intercotyledonary necrosis is accompanied by heavy neutrophil infiltration.[5,336] Diagnosis of Q fever abortion should be based on the presence of characteristic placental lesions with large numbers of rickettsiae and a rising maternal titer. Rickettsieae can be identified in placental impression smears stained with modified Koster's stain, Stamp's modified Ziehl-Neelsen stain, or Gimenez stain as pleomorphic acid-fast coccoid or filamentous organisms in trophoblasts or extracellularly. Complement fixation titers greater than 1:8 in the dam are considered diagnostic. Enzyme-linked immunosorbent assay is rapid and sensitive but requires species-specific peroxidase conjugate for each host species. Laboratory results must be interpreted carefully because *C. burnetii*, also can be isolated from the placenta of normal animals.[5] In one survey of California dairy goats, 24% were seropositive by microagglutination.[337]

43.45.4.3 Pathophysiology

C. burnetii, infection can be transmitted by ixodid or argasid ticks or by ingestion of infected material. The organism replicates in trophoblasts and is often of low pathogenicity in sheep and goats but can result in placentitis with late abortion and shedding of large numbers of rickettsiae.[5]

43.45.4.4 Epidemiology

Q fever is reported in many countries, including the United States and Canada. Abortions typically occur over a 2- to 4-week period and may affect 5% to 50% of the flock.[5] The organism also is infectious for other animals, including humans. Pregnant women should not handle Q fever—infected animals or tissues.

1466
1467

43.45.4.5 Treatment and Control

Aborting does and ewes should be segregated, and abortuses and placentas removed from the premises to prevent oral transmission. Pregnant animals can be treated with tetracycline to reduce the chances of abortion. A carrier state may develop, but abortions do not usually occur in subsequent pregnancies in sheep; they may be more likely to recur in goats.[338] Inactivated vaccines (not commercially available) lessen the chances of rickettsial abortion in sheep and reduce but do not eliminate rickettsial shedding at parturition.[336]

43.45.5 *Campylobacter fetus*, subspecies *fetus*, Abortion

C. fetus, subsp. *fetus*, is one agent of ovine campylobacteriosis (vibriosis) that causes abortion in sheep and sporadic abortion in cattle and goats.[5,266,302]

43.45.5.1 History and Clinical Signs

Infection of ewes causes abortion in the last 6 weeks of pregnancy, stillbirths, and birth of premature lambs. Infected ewes may have fever, diarrhea, depression, and vaginal discharge several days before parturition.[302] In cattle the infection is not associated with infertility (unlike infection with *C. fetus*, subsp. *venerealis*), but sporadic abortions can occur from the fourth to eighth months of gestation.[266]

43.45.5.2 Laboratory Diagnosis

Campylobacter, causes placentitis with cotyledonary necrosis and intercotyledonary edema. The fetus is edematous and may have fibrinous polyserositis. Foci of necrosis up to 2 cm in diameter occur in the liver of approximately 40% of aborted ovine fetuses and, although not pathognomonic, suggest campylobacteriosis.[5,266] Histologic changes include suppurative necrotizing placentitis and fetal bronchopneumonia.[266] Diagnosis is based on culture (which usually requires less than 48 hours)[5] or on microscopic demonstration of the organism.[5]

43.45.5.3 Pathophysiology

C. fetus, subsp. *fetus*, is transmitted by ingestion. The organism localizes in the gallbladder but may invade the pregnant uterus, where it replicates in chorioallantoic trophoblasts. The incubation period in the ewe varies from 7 to 25 days.[5] In the cow, dissemination of the organism to the placenta is less common.[266] In either species, localization in the placenta causes placentitis and fetal bacteremia.[266] Metritis, fetal retention, and maternal peritonitis may occur in the ewe.[5]

43.45.5.4 Epidemiology

Infection with *C. fetus*, subsp. *fetus*, is important in sheep in the United Kingdom, the United States, and New Zealand.[5] Fetal infection is most common during the last 2 months of gestation. Outbreaks of abortion tend to occur in 4- to 5-year cycles.[5] Infection is highly contagious in confined ewes, and the abortion rate may approach 70% but is more commonly approximately 25%.[5,266,302]

43.45.5.5 Treatment and Control

Abortion outbreaks can be treated with daily intramuscular injections of procaine penicillin G (22,000 IU/kg) and dihydrostreptomycin (11 to 22 mg/kg) or with oxytetracycline in the feed (75 mg/head/day).[5] Metritis is rarely fatal in the ewe. Generally, affected ewes abort only once and therefore they may be retained as breeding stock.[266] Ovine campylobacteriosis can be controlled by the use of a killed adjuvanted bacterin at breeding and 60 to 90 days later.[5]

43.45.6 *Campylobacter jejuni*, Abortion

Campylobacter jejuni, is the other agent of ovine *Campylobacter (Vibrio)*, abortion. *C. jejuni*, is an enteric pathogen that causes enteritis and diarrhea in many species. Only in sheep is placental and fetal infection common. This organism has been associated occasionally with abortion in cattle and goats.[5,11,266,339,340]

43.45.6.1 History and Clinical Signs

Ovine infection with *C. jejuni*, is clinically indistinguishable from that with *C. fetus*, subsp. *fetus*.,

43.45.6.2 Laboratory Diagnosis

Aborted fetuses are autolyzed and frequently lack specific gross lesions. Cotyledons are mottled yellow to tan, but the intercotyledonary membranes are grossly normal. Histologically necrosis occurs in chorionic villi with arteriolitis and numerous leukocytes in the lamina propria. Purulent bronchopneumonia is a common histologic finding in the fetus.[341]

C. jejuni, can be distinguished from other *Campylobacter*, species by growth at 42° C (107.3° F), resistance to cephalothin, inhibition by nalidixic acid, and the presence of heat-labile glycoprotein surface antigen 1, which does not occur in *C. fetus*, subsp. *venerealis*, or *C. fetus*, subsp. *fetus*., Placenta or fetal tissues should

be cultured on *Campylobacter*, agar with incorporated cefoperazone, vancomycin, and amphotericin B (CVA medium) at 42° C (107.3° F).[340,341]

43.45.6.3 Pathophysiology

Intravenous inoculation of pregnant ewes with *C. jejuni*, at 114 and 123 days of pregnancy consistently induced abortion 7 to 12 days later in one study.[341]

43.45.6.4 Epidemiology and Control

C. jejuni, is ubiquitous. Certain strains have been associated with an abortion rate as high as 80%, but usually fewer than 20% of the animals in the flock abort.[341] Aborted tissue is infectious for humans and should be handled with caution. Treatment and control of ovine infection with *C. jejuni*, are similar to those for *C. fetus*, subsp. *fetus*.,

43.45.7 *Brucella melitensis*, Abortion

Brucella melitensis, causes abortion in goats and sheep and less commonly in cattle.[5] Infection is associated with late abortion, stillbirth, or birth of weak kids or lambs.[5,283] Necropsy findings include severe placentitis and fetal serositis.[5,302] The disease is diagnosed by culture or demonstration of the organism in tissue or by maternal serology (complement fixation test).[5] Animals are infected by ingestion, and, after bacteremia, replication occurs in chorioallantoic trophoblasts.[5,285] Infection with *B. melitensis*, is important in Mediterranean countries and in Central and South America but is rare in the United States.[283,302] Suspected cases should be reported to state and federal authorities. Human infection with *B. melitensis*, can be very severe.

43.45.8 *Brucella ovis*, Abortion

Brucella ovis, infects only sheep. Epididymitis in rams is the most common manifestation of infection. Ewes seldom show clinical evidence of infection; late abortions, stillbirths, and delivery of weak lambs are rare.[5,266] 1467
Fetal and placental lesions resemble those induced by *B. abortus*., Diagnosis is based on culture or on 1468
demonstration of the organism in tissue. Serology (complement fixation) can identify infected animals. However, not all ewes showing a rise in complement fixation titer at parturition deliver infected lambs. In addition, ewes can maintain elevated titers for months or years after exposure to *B. ovis*., Therefore *B. ovis*, abortion should not be diagnosed on the basis of complement fixation testing alone.[266]

Infection is thought to occur by the conjunctival route.[302] The bacterium has low virulence for the ewe but may replicate in chorioallantoic trophoblasts, resulting in placentitis and fetal bacteremia.[285] *B. ovis*, infection has been reported from Europe, Africa, Australia, New Zealand, and the western United States.

43.45.9 *Chlamydia psittaci*, Abortion (Enzootic Abortion of Ewes)

C. psittaci, is a major cause of abortion in sheep and goats.[5,266] Ovine chlamydial abortion is called *enzootic abortion of ewes. Chlamydia*, may cause abortion in cattle[266] but is not the cause of epizootic bovine (foothill) abortion.

43.45.9.1 History and Clinical Signs

Chlamydiosis is best characterized in sheep and goats. Abortions or stillbirths with placentitis usually occur in the fourth to fifth months of gestation. The dam seldom shows signs of illness but may have serosanguineous vaginal discharge several days before and after parturition.[5] Other animals in the flock may be affected by arthritis or pneumonia.[342]

43.45.9.2 Laboratory Diagnosis

Placentitis is the most consistent necropsy finding in chlamydial abortion. Necrosis occurs in cotyledons; the intercotyledonary placenta is thickened with accumulation of red exudate.[266,342] The fetus has no specific gross lesions.[266,342] Histologically, necrotizing placentitis is accompanied by nonsuppurative vasculitis. Nonsuppurative meningoencephalitis, necrotizing hepatitis, and proliferation of mononuclear cells in spleen and lymph nodes are other histologic findings that may occur in the fetus.[266,343]

Diagnosis of chlamydial abortion should be based on identification of the organism and the presence of typical placental lesions. Chlamydiae appear in placental impression smears stained with Giemsa, Gimenez, or modified Ziehl-Neelsen stains as 200-nm dark red spheric bodies in the cytoplasm of trophoblasts.[5,266] The organism can be positively identified by FA tests on cytologic preparations, cryostat sections of placenta or other fetal tissues, or cultures. *Chlamydia*, grows in chick embryos in 1 to 6 weeks, but cell culture using mouse L cells requires only 2 to 10 days.[266]

Abortion or delivery of chlamydial-infected fetuses induces a rise in serum titer that peaks in 2 to 3 weeks.[266] Paired sera should be collected at abortion and 3 weeks later. Maternal titers greater than 1:32 generally indicate recent active infection.[344] Complement fixation is the standard serologic test for the dam; indirect immunofluorescence and enzyme-linked immunosorbent assay are also used.[345] Double immunodiffusion can be performed on fetal fluids.[266]

43.45.9.3 Pathophysiology

Chlamydiae reside in the intestinal tract and are also shed from the genital tract of infected animals before and after parturition. Ingestion is the main form of transmission.[5,346] In sheep and goats, abortion occurs 4 to 8 weeks after experimental infection,[342] but the fetus is not susceptible until the last third of gestation.[5]

High maternal antibody titers do not prevent abortion or stillbirth, but experimental work suggests that cell-mediated immunity is protective.[347] Infection with small numbers of *Chlamydia*, organisms seldom

stimulates adequate cell-mediated immunity and consequently may be more likely to cause abortion than infection with numerous organisms.[5]

43.45.9.4 Epidemiology

Chlamydial abortion has been reported from most major sheep- or goat-producing countries. *C. psittaci*, also may infect other animals, including human beings. Pregnant women should not handle infected animals or tissues. The abortion rate in sheep is usually approximately 5%[266] but may be up to 30% or more in goats.[5,342] Although abortions usually occur 1 to 2 months after infection in sheep, the incubation period in goats may be as short as 2 weeks.[344]

43.45.9.5 Treatment and Control

Aborting does or ewes should be segregated, and abortuses and placentas should be removed from the premises to avoid oral transmission. Oxytetracycline therapy (80 to 450 mg/head every day in feed or water, or long-acting oxytetracycline injected subcutaneously at a dose of 20 mg/kg twice weekly until the last month of gestation)[5] reduces the number of abortions and stillbirths in sheep[347] and goats, particularly if instituted in the first half of pregnancy.[5] However, short-term treatment does not eradicate infection or prevent chlamydial shedding at parturition and should be reserved for abortion outbreaks.[348] Most ewes develop cell-mediated immunity, which eliminates the organism from the genital tract by 3 months after lambing and protects against abortion for approximately 3 years.[5,348] Does are more likely than ewes to have placental retention and metritis after abortion.[346] Killed vaccines* can be used in enzootic areas 4 to 6 weeks before breeding but are not 100% effective. Experimentally avirulent live vaccines have been used with success.

* Animal Health Division, Shawnee, KS.

43.45.10 Toxoplasmosis Abortion

Toxoplasma gondii, is a ubiquitous protozoan that is a major abortifacient in sheep and goats but only rarely causes abortion in cattle or horses.

43.45.10.1 History and Clinical Signs

Infection does not cause clinical illness in the adult but may result in embryonic death, fetal death and abortion, stillbirth, or birth of weak, nonviable lambs or kids.

43.45.10.2 Laboratory Diagnosis

The most characteristic gross lesion of toxoplasmosis is the presence of white, chalky foci of necrosis and calcification up to 2 mm in diameter in cotyledons.[349–351] The intercotyledonary areas of the placenta are grossly normal. Specific gross lesions are not observed in the aborted fetus, but histologically most have nonsuppurative encephalomyelitis[350] and many also have pneumonia, myocarditis, or hepatitis. Tachyzoites may be found in placenta or other fetal tissues but are not numerous.[351,352] The tachyzoites are oval, 2 to 4 by 4 to 8 mm, with a central nucleus and appear larger in impression smears than in paraffin sections. Several

serologic tests, including the modified agglutination test, indirect FA test, Sabin Feldman dye test, indirect hemagglutination test, and enzyme-linked immunosorbent assay, reliably detect toxoplasmosis in pleural or amniotic fluid or presuckling serum from nondecomposed fetuses.[266,353,354] The modified agglutination test is commercially available, safer, and more sensitive than the dye test. Fetal antibodies to *T. gondii*, can be detected 35 days after infection.[349] Absence of fetal antibody does not always preclude a diagnosis of toxoplasmosis.[266] High maternal titers are not diagnostic of toxoplasmal abortion, but lack of titer eliminates toxoplasmosis as the cause for abortion.[349] The peroxidase-antiperoxidase method for detecting *Toxoplasma*, antigen in fetal tissues or placenta is reliable even in autolyzed fetuses. Fetal heart, lung, brain, spinal cord, skeletal muscle, and placenta are the preferred specimens for the peroxidase-antiperoxidase method and should not be held in formalin more than 2 days before paraffin embedding.[352] *T. gondii*, can be isolated by intraperitoneal inoculation of placental or fetal tissue suspensions into mice.[266]

43.45.10.3 Pathophysiology

Placental infection occurs approximately 14 days after ingestion of oocysts.[352] Infection acquired before 50 days' gestation may result in embryonic death and resorption. Infection between 60 and 100 days' gestation usually causes fetal death or birth of weak lambs. Infection during the last month of gestation often has no apparent effect on the fetus.[349] In experimental infection of ewes between 6 and 14 weeks of pregnancy, abortions occurred 1 to 2 months after inoculation.[354] In natural infections, most abortions occur 1 month before parturition.[349]

43.45.10.4 Epidemiology

Toxoplasmosis is a major cause of ovine abortion in many sheep-raising countries, including the United States.[350,351,355] Sheep are infected by ingestion of oocysts from feed or grass contaminated with cat feces. Most ewes are infected by 4 years of age.[356] Aborted tissues may be infectious for humans and should be handled with caution.

43.45.10.5 Control

Infected ewes or does seldom abort from toxoplasmosis in subsequent pregnancies.[350] The prevalence of abortion can be reduced by avoiding contamination of feedstuffs with feline feces. Cats should not be allowed to eat placentas or carcasses that may contain tachyzoites or tissue cysts. In endemic areas, exposing replacement ewes to aborting ewes may provide immunity before breeding age.[5]

43.45.11 *Mycoplasma*, Abortion

Treatment of *Mycoplasma*, infection in goats is usually not recommended because treated animals may remain carriers. The infection is eliminated from the herd by testing milk and slaughtering infected animals.[300]

43.45.12 Leptosirosis

Serovar *Leptospira*, Pomona is the major ovine isolate,[266] but *Leptospira*, Bratislava and *Leptospira*, Hardjo have also been isolated from sheep.[266] *Leptospira*, Grippotyphosa is the major caprine isolate.[5] Leptospiral abortion is less common in sheep and goats than in cattle.

43.45.12.1 CAMELIDS

The incidence of abortion in llamas and alpacas is low. Infectious causes in North America include leptospirosis, toxoplasmosis, chlamydiosis, and other nonspecific uterine infections.[191] Bovine virus diarrhea is considered an emerging disease in alpaca herds and may be responsible for some of the early pregnancy losses and abortions in some herds. Diagnostic workup for abortion in camelids is similar to that described in this chapter for other species.

43.46 MALE REPRODUCTIVE DISORDERS

STEVEN P. BRINSKO,

TERRY L. BLANCHARD,

DICKSON D. VARNER,

43.46.1 INFERTILITY CAUSED BY DISEASES OF THE PENIS AND PREPUCE

43.46.1.1 PENILE INJURY

43.46.1.1.1 STALLION

43.46.1.1.1.1 Definition and Etiology

If the penis is injured while erect, it may swell rapidly and massively from vascular rupture and hemorrhage. Hemorrhage usually originates from the superficial penile vessels in the plexus external to the tunica albuginea.[357] The stallion may be kicked during mating, or hematomas may follow breeding a mare with a tightly sutured vulva or may be induced if the mare moves suddenly during mating.[358,359] Injuries can also occur during semen collection if proper techniques are not employed.

43.46.1.1.1.2 Clinical Signs and Differential Diagnoses

Cutaneous abrasions, lacerations, and visible hemorrhage may be present. Paraphimosis occurs when enlargement is sufficient to prevent retraction of the penis through the preputial ring.[357] Edema may extend to the scrotum and interfere with thermoregulation of the testes.[360] Venous thrombosis, lymphatic occlusion, excoriation, and swelling accompany chronic inflammation.[357] Hemorrhage from

the corpus cavernosum penis (CCP) is uncommon. Rupture of the surrounding tunica albuginea, when healed, may develop fibrous adhesions that lead to penile deviation during erection.

43.46.1.1.1.3 Treatment and Prognosis

Immediate treatment is directed toward reducing edema and inflammation and controlling infection. Treatment is similar to that described for paraphimosis in a later section. Sexual rest is indicated until the lesions have healed.[361] If treatment is initiated early and paraphimosis does not occur, the prognosis for recovery is good.[357,359]

43.46.1.1.2 BULL

43.46.1.1.2.1 Definition and Etiology

The penis of bulls is susceptible to injury during mating. The vigorous thrust that accompanies copulation predisposes the penis and prepuce to excoriations, lacerations, and bruising. Rupture of the tunica albuginea (penile hematoma or "broken penis") occurs if the penis is misdirected during copulation.[362] Penile hematomas most commonly occur in young, sexually aggressive bulls. Injuries occur when these bulls attempt to breed heifers or cows that are not receptive, when females falter or collapse under the weight of the bull, or when the bull slips because of poor footing.[358] During copulatory thrusting in which the penis is bent, the tunica albuginea ruptures on the dorsal or dorsolateral surface of the penis opposite the attachment of the retractor penis muscle. Presumably, CCP pressure rapidly increases as the functionally closed system is compressed during bending to rupture the tunica albuginea. Experiments with fresh postmortem specimens indicated that a CCP pressure of 1180 to 1720 psi was required to rupture the tunica albuginea. Tearing virtually always occurred at the site described in naturally occurring cases. Mean peak CCP pressure recorded during normal coitus (275 psi) occurs when cavernous spaces fill with a relatively small volume of blood, perhaps as little as 110 mL.[360] Blood escapes from the CCP into the surrounding tissue.[357] The size of penile hematomas may be related to the number of repeated trials made by the bull before cessation of attempts at mating. Larger hematomas restrict full retraction of the penis and result in prolapse of the prepuce from the sheath. Secondary preputial injury is common.[357]

1469
1470

43.46.1.1.2.2 Clinical Signs and Differential Diagnoses

Diagnosis of penile hematoma is made based on the presence of a swelling immediately cranial to the scrotum. Initially it is soft, fluctuant, and painful, and becomes firm as clot organization and fibrin formation progress.[358] The main differential diagnosis is extensive preputial laceration. If a distance of more than two handbreadths is present between the scrotum and the enlargement, the swelling is more likely to be a preputial laceration. Other differential diagnoses include rupture of the urethra, abdominal hernia, and chronic, fibrous adhesions. Dysuria usually does not occur in conjunction with penile hematoma. Other signs of urethral rupture or blockage, such as extensive preputial cellulitis and "water belly," elevated blood levels of urea nitrogen and creatinine, and tissue necrosis do not occur. Abscess formation of penile hematomas sometimes occurs. A soft, fluxuant center is characteristic of an abscess. Occasionally, differentiation between blood clot and abscess may be difficult. An aseptic tap can be

done to determine the character of the fluid, but the risk of inducing an abscess in a sterile hematoma is great and a tap should be used only as a last diagnostic resort or just before surgery.

If penile hematoma has been present for longer than 2 weeks, fibrous adhesions may form that prevent penile extension. Adhesions are frequent sequelae of abscesses, and have also been reported to occur secondary to infiltration of local anesthetics to block the dorsal nerves of the penis.[358] Another sequela is the development of venous shunts that communicate between the CCP and either the peripenile vasculature or the corpus spongiosum penis (CSP).[357,363] Such vascular shunts result in rapid drainage of blood from the CCP and impotence caused by failure to achieve or maintain full erection. If the dorsal nerves of the penis are damaged, sensation of the distal penis is lost or deficient and results in failure of the bull to successfully seek out the female's vagina and/or ejaculate. Organization of the portion of the blood clot (thrombosis) within the body of the CCP may result in functional blockage of engorgement of the more distal cavernous spaces, preventing full erection.

43.46.1.1.2.3

Treatment and Prognosis

Treatment of penile hematomas should be aimed not only at restoring the bull to usefulness, but also at preventing recurrence. Approximately 50% of bulls with hematomas that are treated conservatively (i.e., nonsurgically) are reported to return successfully to breeding.[357] Some theriogenologists feel that small hematomas (less than football size) do not require surgery.[364] However, Auburn University faculty report that surgical intervention is required to optimize chances of full recovery. Surgical correction has the advantages of (1) removing the blood clot before extensive fibrous adhesions develop, (2) permitting removal of blood clot from within the body of the CCP itself, thereby reducing the chance of blockage of cavernous filling, and (3) suturing the tunica albuginea, which should reduce the chance of recurrence of the condition after return to service and the likelihood of development of vascular shunts that will prevent complete filling of the CCP. Surgical intervention is not recommended before coagulation of the extravasated blood. Once significant fibrin formation is present, the prognosis for successful correction is greatly reduced and should be attempted only in valuable bulls.[357]

Additional recommendations before electing surgical intervention include extending the penis manually. Cases in which the penis can be extended from 6 to 8 inches or more beyond the sheath orifice, and in which penile sensation remains, carry a better prognosis.[365] If engorgement of the distal penis does not occur after careful stimulation with the electroejaculator, blockage of the CCP should be suspected and reduces the prognosis. Finally, cases with abscesses are poor risks because severe restrictive adhesions usually develop.[357]

Regardless of whether surgical or conservative intervention is selected for a penile hematoma, the bull should be treated with high levels of systemic antibiotics in an attempt to prevent abscess formation. Penicillin is a good choice because abscesses are usually caused by *A. pyogenes*., Postsurgical complications are much the same as those that may occur without surgery, but these adverse consequences are reported to occur less frequently after surgery. Bulls should not be returned to service for 2 to 3 months after treatment.[357,358]

43.46.1.1.3 RAM AND BUCK

Adhesions of the penis and prepuce caused by trauma are uncommon in adult small ruminants. The penis does not separate from the prepuce until puberty and cannot be extended before this time (4 to 5 months of age in bucks).[366] Most traumatic lesions of the penis or prepuce in sheep and Angora goats are from shearing injuries.[264] Blockage of the urethral process by calculi can cause necrosis and sloughing of tissue that may extend into the glans penis.[367] Fighting among horned animals may result in injury to the external genitalia, including the penis. In dairy goats the intersex condition can result in congenital malformation of the penis and prepuce (hypospadias).[368]

43.46.1.2 PHIMOSIS AND INJURY TO THE PREPUCE

43.46.1.2.1 STALLION

43.46.1.2.1.1 Definition and Etiology

Stenosis of the preputial orifice prevents extension of the penis. The defect is likely to be a sequela to an injury that results in cicatrix formation, but may rarely be congenital.[357,358] Tumors (such as melanoma or SCC) or *Habronema*, granulomas may encroach on the preputial cavity, thereby preventing penile extension.[369]

1470

1471

43.46.1.2.1.2 Clinical Signs and Differential Diagnoses

Acute posthitis often accompanies injuries to the prepuce or infections such as equine coital exanthema and dourine.[357,358] Edema is common with acute posthitis, particularly after trauma. Gravitational effects typically worsen the preputial edema, which may induce prolapse of the external prepuce, trapping the penis in the swollen internal prepuce with a constricting preputial ring.[357] Cicatricial scar formation may follow, narrowing the diameter of the preputial orifice. Transpreputial ultrasound examination may be of benefit in differentiating tumors or abscesses from inflammatory edema or hemorrhage. Containment of the penis within the prepuce causes preputial urine accumulation, worsening balanoposthitis and secondary bacterial infection. The extended chronic inflammation leads to cicatrix formation with phimosis.[370]

43.46.1.2.1.3 Treatment and Prognosis

Preputial edema can be relieved by administration of diuretics and exercise. Application of crushed ice in plastic bags or preputial immersion in cold water may reduce inflammatory edema if performed soon after injury. Subsequently, emollient antibiotic preparations and hydrotherapy can be used to massage injured tissues and reduce edema. Systemic antibiotics and nonsteroidal antiinflammatory drugs are indicated to control secondary infection and inflammation. Sexual rest is indicated until the lesions have healed.[361]

A biopsy can be procured from encroaching tumors to identify cell types and improve prognostic capability.[361] Cicatricial scars can sometimes be successfully removed surgically. Once inflammation and infection are resolved with local or systemic antibiotic and antiinflammatory drug treatment, incision of the ventral aspect of the preputial orifice (preputiotomy) may be necessary to enlarge the opening sufficiently to permit penile extension.[371] Large tumors or granulomas of the prepuce can sometimes be successfully removed surgically if sufficient elastic and membranous tissue remain to permit normal penile extension and retraction.[361] The prognosis for return to breeding soundness, however, is guarded when surgery must be performed. Postsurgical adhesions may develop that result in continued phimosis or penile deviation. In cases of habronemiasis, treatment with systemic insecticides or ivermectin may be indicated to kill remaining parasitic larvae.[369] Congenital abnormalities can seldom be corrected surgically.

43.46.1.2.2

BULL

43.46.1.2.2.1

Definition and Etiology

Trauma to the prepuce involving the elastic lamellar layers may prevent the required flexibility of the prepuce to permit penile extension. Breed predisposition to preputial injuries corresponds to genetic differences in pendulousness of the sheath and development of the muscles responsible for retraction of the prepuce. The polled gene is linked to weak or failed development of the preputial muscles, leading to habitual preputial eversion, which predisposes to injury. Brahman-blooded cattle have the added predisposition of a loose, pendulant sheath. With their tendency to partially evert the preputial membrane through the sheath orifice, they are at greater risk for damaging the prepuce accidentally than those breeds of cattle in which the sheath is held in close apposition to the abdominal wall.[357,358,372]

Inability of the bull to extend the penis most commonly follows injury to the penis and prepuce that culminates in strictures or adhesions that restrict normal penile movement.[357,358,373–376] Other causes of phimosis include congenital anomalies such as a short penis, a short retractor penis muscle, and developmental abnormalities of the reproductive tract such as occur in pseudohermaphrodites.[358,374]

43.46.1.2.2.2

Clinical Signs and Differential Diagnoses

The more common preputial injuries are contusions, abrasions, lacerations, and frostbite. When the injured prepuce can be retracted, the injury may not be suspected unless hemorrhage is noted from the sheath or the bull is observed having difficulty during breeding. Although minor injuries may spontaneously resolve, more extensive injuries commonly progress to abscess formation and fibrous stricture formation.[357,364,375,376] Extension and examination of the penis may result in further injury if the case is complicated by phimosis. In such cases an attempt to extend the penis to facilitate examination is contraindicated because forcibly stretching the prepuce will extend the laceration and spread infection to uncontaminated areas.[357]

43.46.1.2.2.3

Treatment and Prognosis

Treatment of preputial injuries in the bull may be either medical or surgical. With few exceptions, such as fresh avulsive lacerations in the fornix area, surgical intervention carries a better prognosis when medical treatment is first carried out to control inflammation and infection.[375] The healing leaves more normal tissue to be identified and salvaged during surgery. In cases in which the injured prepuce is retracted into the preputial cavity, digital or speculum examination can be done in an attempt to locate lesions and determine the extent and depth of tissue involvement. Systemic administration of antibiotic is necessary to reduce the incidence of abscess formation preoperatively, and antibiotic should be administered through the surgical and postsurgical periods if surgery is elected. When the injured prepuce remains prolapsed in presented bulls, the first consideration is to attempt to return the prepuce to the preputial cavity.[357,375] The exposed epithelial covering of the prepuce is easily injured and becomes quite edematous and friable because of its pendent location. Hydrotherapy for 20 to 30 minutes may be helpful in cleansing the exposed prepuce and reducing edema. After the prepuce is gently cleansed and the degree of patency of the lumen is determined, a protective emollient preparation is used to massage edematous swelling upward out of the prolapse.[375] Massage for 15 to 30 minutes may be required to reduce swelling sufficiently to permit the prepuce to be returned to the preputial cavity. If the prolapsed prepuce can be returned to the sheath, a retention technique should be used to prevent reprolapse. With the prepuce in place, a tube can be inserted just beyond the swollen internal portion of the prepuce to avoid urine retention. The tube is taped in place at the external preputial orifice. Tape should not extend past the proximal end of the tube, or urine retention and migration into peripreputial tissue will occur. If this technique will not retain the prepuce, a purse-string suture in the skin of the sheath orifice can be used.[357] It should be tight enough to retain the prepuce but leave sufficient space for urine to pass freely. To avoid suture abscesses and stricture formation, the sheath should be clipped and prepared aseptically for suture placement, and sutures should be removed as soon as swelling and inflammation subside. If the prolapsed prepuce cannot be returned to the preputial cavity, the prognosis for correction without surgery is guarded. After cleansing as described previously, a portion of stockinette is coated in ointment and is applied over the prepuce. A diaper constructed from heavy canvas or burlap with straps and centrally located perforations for urine drainage is applied under the prepuce and tied up over the back to hold the prepuce gently next to the abdominal wall to decrease gravitational edema. It is changed daily until infection and swelling are controlled and the prepuce is either returned to the sheath or surgery is performed. Alternatively, the prolapsed portion of the prepuce can be wrapped in medicated gauze followed by application of a gentle but firm pressure wrap around a section of tubing. The pressure wrap is left in place temporarily to reduce edema, at which time the wrap is removed and the prepuce replaced into the sheath.[375]

1471

1472

Once sufficient healing has occurred the necessity for surgery is determined by extending the penis.[357] Adhesions most commonly take the form of encircling cicatricial strictures that must be removed surgically. Guidelines suggested for predicting successful outcome of surgery include the following:

- A minimum of 5 cm of normal prepuce should be present on either side of the surgical site, or proper unfolding may not be possible after surgery
- Free prepuce remaining after surgery should be at least twice the length of the free portion of the penis, or the prepuce may be too short to permit full penile extension.

Presurgical and postsurgical considerations, and surgical techniques used to correct phimosis, are described by Walker and Vaughan.[357]

Congenital anomalies contributing to phimosis are diagnosed based on physical examination of the entire reproductive tract. Abnormal karyotypes may be helpful in determining causes. If the penis cannot be extended with the techniques described and if evidence of injury or adhesions is not present, congenitally short penis or retractor penis muscles should be suspected.[358] Accompanying history may provide information that the bull could copulate when young, but as he aged his abdomen progressively enlarged, causing the penis to be relatively of insufficient length to effect copulation.[358]

43.46.1.2.3 RAM AND BUCK

Phimosis is uncommon in small ruminants. It may be congenital, or acquired as a result of adhesions or preputial scarring associated with trauma or balanoposthitis. This condition is diagnosed during the physical examination and/or by observing the animal during the breeding process. If phimosis results from acute inflammation of the prepuce (posthitis), it may resolve when the preputial swelling reduces. However, the prognosis is guarded until scarring can be evaluated. Phimosis may also be congenital in small ruminants.[367]

43.46.1.3 PARAPHIMOSIS

43.46.1.3.1 STALLION

43.46.1.3.1.1 Definition and Etiology

When injury of the penis and the laminae of the prepuce is attended by hemorrhage and edema, paraphimosis (the inability to retract the penis into the prepuce) is likely to occur.[357] Prolonged penile prolapse, caused by debility or paralysis after the use of some tranquilizers, usually culminates in extensive penile trauma.[377,378] Protracted priapism (persistent erection) can lead to penile trauma and complications similar to those of penile prolapse.[379] Penile paralysis and priapism are distinctly different conditions. Penile paralysis develops secondary to insufficient tone of the retractor penis muscles.[380] Motor innervation of the retractor penis muscles in stallions is believed to be solely supplied by α-adrenergic fibers. When α-adrenergic blocking drugs such as phenothiazine-derivative tranquilizers are administered, paralysis of these muscles can cause penile prolapse.[381] The prolapsed penis is flaccid and cannot be maintained in the retracted position.[357,380] Priapism is a persistent erection without sexual arousal and is initially unassociated with penile paralysis. It develops from engorgement of the CCP with blood, and although the horse may not achieve a full erection, its penis is not flaccid.[382,383] When the penis fails to detumesce, CO_2 tension in the CCP increases, resulting in increased blood viscosity and subsequent venous occlusion where collecting veins join the cavernous spaces. Edematous swelling of corporeal trabeculae further reduces venous outflow, thus increasing the likelihood of irreversible venous occlusion, fibrosis of the cavernous trabeculae, and arteriolar occlusion. Disruption of the arteriovenous supply and fibrosis of the CCP prevent subsequent erections.[361,384]

43.46.1.3.1.2

Clinical Signs and Differential Diagnoses

Penile paralysis has been reported in exhausted or debilitated horses, in horses with myelitis or spinal injury, and in horses with severe injury to the penis.[357,377] Traumatic inflammatory edema often results in severe swelling of preputial membranes that prevents retraction of the penis into the prepuce. The inability to retract the penis results in further gravitationally induced edema, and as the problem worsens, edematous fluid eventually oozes through the increasingly fragile penile and preputial integument. Cellulitis develops and the integument becomes thickened, inelastic, desiccated, necrotic, and irreversibly damaged.[357,361] In cases of long-standing priapism, the distal end of the penis becomes cool to the touch, and the clot may become palpable in the body of the CCP as fibrin organization occurs. The organized clot may be visible on ultrasound examination.[379]

43.46.1.3.1.3

Treatment and Prognosis

Prognosis for recovery becomes guarded to grave the more chronic the paraphimosis becomes. Principles of treatment are similar to those described for the bull. To maintain the penis within the prepuce, a temporary purse-string suture of heavy Vetafil can be placed near the preputial orifice. Alternatively, a padded plastic bottle from which the bottom has been removed can be used to support penile hematomas.[385] After the injured penis is dressed, the bottle is placed over it and pushed back into the sheath. The bottle is held in place with straps running over the lumbar area and on either side of the scrotum up over the tail head. Voiding of urine occurs through the bottle. The apparatus should be cleaned and replaced twice daily until the penis can be retained in the retracted position. If the penis cannot be returned into the prepuce, an external support for the prolapse should be applied. Prolonged penile prolapse may result in excess gravitational pull that damages smooth muscle cells, the retractor penis muscle, and the pudendal nerves[357,380]; such sequelae decrease the prognosis for recovery and return to a successful breeding career. Chronic, refractory penile prolapse results in severe balanoposthitis that may require circumcision or penile amputation. Surgical penile retraction (the Bolz technique) is described by Walker and Vaughan.[357]

Medical treatment of horses with priapism has generally been unsuccessful.[361,382] In cases of drug-induced priapism seen within 2 to 4 hours of occurrence, slow intravenous injection of 8 mg of benzotropine mesylate may cause detumescence and penile retraction to occur.[386] If the animal is not seen immediately, treatment is the same as for traumatic paraphimosis. Rapid detumescence can be induced by injecting 10 mg of phenylephrine into the CCP, even in long-standing cases. However, the detumescence may be only transient. Flushing the CCP with heparinized lactated Ringer's solution through 12-gauge needles to remove sludged blood has been recommended for horses with priapism of 12 to 24 hours' duration that have not responded to medical treatment.[361] If a blood clot forms in the CCP, the prognosis is poor and amputation may be necessary. Some stallions, if severe nerve damage does not occur, may regain the ability to breed and ejaculate when assisted with placement of the penis into either the vagina of the mare or an artificial vagina. When the stallion does not regain the ability to completely retract the penis into the sheath, continued penile trauma is likely to result in damage to the sensory nerves to the glans penis. Such horses may achieve an erection but may have difficulty both in seeking the mare's vulva for intromission and in ejaculating. Ultrasonography of the CCP to detect cavernosal fibrosis may be useful in assessing prognosis for recovery from priapism. Prognosis for

recovery is good once penile retraction occurs, but breeding should not be permitted until healing is complete.

43.46.1.3.2 BULL

43.46.1.3.2.1 Definition and Etiology

Paraphimosis is less common than phimosis in the bull. The conditions have some common causes, but for paraphimosis the causes also include penile tumors, parasitic invasion, traumatic or spinal disease affecting innervation of structures responsible for penile retraction, inadvertently severed retractor penis muscles, and physical trapping of the penis by a constricted prepuce after injury. Penile paralysis and paraphimosis sometimes occur as a result of spinal injury or disease, and in rabies cases as well.[357,358,373–376,387]

43.46.1.3.2.2 Clinical Signs and Differential Diagnoses

Persistent exposure of the penis results in congestion, inflammation, and necrosis of the penile integument.[358,373,374]

43.46.1.3.2.3 Treatment and Prognosis

Management of the prepuce has been discussed. Exposed portions of the penis should be frequently cleansed and protected by a bandage soaked in oily antibiotic preparations. The prolapsed penis should be supported close to the abdomen to reduce edema. The penis should be returned to the sheath as soon as possible and mechanically restrained if necessary. If the ability to retract the penis does not return in a few days, prognosis for recovery is poor.[357]

43.46.1.3.3 RAM AND BUCK

Paraphimosis is uncommon in small ruminants. The diagnosis is obvious, although the cause may not be. Treatment involves the same principles as in the bull. Prognosis is guarded and correlates with the degree of injury and necrosis at the time the condition is discovered.

43.47 URETHRAL INJURY AND URETHRITIS

43.47.1 STALLION

43.47.1.1 Clinical Signs and Differential Diagnoses

Traumatic injuries to the urethral process are usually obvious and are characterized by hemorrhage. *Habronema*, granulomas are firm and friable. Ulcers of the urethral process often become secondarily invaded with bacteria such as *Pseudomonas*, species. Parasitic lesions tend to regress during winter, but if untreated they may mineralize and result in recurrence of hemospermia during the following breeding season.[388]

Bacterial urethritis may be associated with hemospermia.[389] Lesions can occur throughout the urethra, including the pelvic urethra in the area of the ejaculatory ducts. Diagnosis is based on demonstration of the lesions by fiberoptic examination.[361] Ultrasonography and fractionation of the ejaculate may be helpful in eliminating involvement of the accessory sex glands.[390]

Urethral inflammation and lacerations may result in fibrous strictures.[389] Strictures are often painful and may separate and bleed during urination and ejaculation. Bacteriologic culture of the urethra, urine, and semen; fiberoptic examination; and histologic examination of biopsies of lesions are helpful in making a diagnosis.[5] Strictures in the distal urethra may be identified by contrast radiography of the extended penile urethra.[357,389]

Clinical signs of uroliths include dribbling of urine with chronic cystitis, dysuria and stranguria, occasional hematuria, recurrent colic, and a stilted, painful gait in the hindquarters. Penile protrusion is frequent or constant in cases of chronic, involuntary escape of urine.[357] Diagnosis is by urinalysis, revealing the characteristic crystals, red and white blood cells, and bacteria. Urethral calculi typically restrict the passage of urethral catheters. Bladder calculi may be palpated per rectum or visualized by ultrasonography.[357,388]

43.47.1.2

Treatment and Prognosis

Treatment of urethral injuries involves first removing inciting factors such as a tight stallion ring. Sexual rest is indicated while palliative therapy is given. The ability to void urine should also be established. Systemic treatment with antibiotics that are eliminated in the urine may be useful as a prophylactic measure or in cases in which secondary bacterial invasion has occurred. More severe cases of urethritis may be treated locally either by infusion of oily antibiotic preparations through sterile, rubber urethral catheters passed to the area of the seminal colliculus of the pelvic urethra, or alternatively by insertion of soluble suppositories through a perineal urethrostomy. After resolution of the urethritis, the urethrostomy is allowed to heal by granulation.[389] Lacerations of the proximal urethra that result in hemospermia can be treated by perineal incision into the corpus spongiosum urethra (CSU) or by perineal corpus spongiotomy in which the CSP is incised but the incision is not extended into the urethra. These surgeries are believed to prevent stretching of the urethra when engorgement of the corpus spongiosum occurs during urination or erection. Repeated stretching is thought to prevent urethral lacerations from healing.[391]

Inflammation of the urethral process may respond to local antibiotic salves. Treatment of parasitic granulomas with ivermectin speeds resolution of these cases.[369,392,393] Larger, nonresolving granulomas with mineralization may require surgical removal.[394] The skin of the urethral process should be rolled inward when sutured to the mucous membrane to prevent eversion that predisposes it to reinjury after healing. Remaining hemorrhagic or ulcerative lesions are lightly cauterized with silver nitrate.[388] More proximally located nonresolving urethral strictures, prolapsed subepithelial vessels, or ulcers can be removed surgically. Leave as much normal urethral mucosa as possible to avoid postsurgical stricture formation.[389]

Calculi lodged within the lumen of the pelvic urethra can be removed via perineal urethrostomy. Treatment for urethral calculi is described in the discussion of diseases of the urinary system, Chapter 34.

43.47.2 BULL

43.47.2.1 Definition and Etiology

Urolithiasis is the primary problem affecting the urinary system that may interfere with normal function of the reproductive tract of the bull.[395] It is of less importance in bulls than in steers but occasionally occurs and may result in hematuria or urethral obstruction.[357,358] Urolithiasis is thoroughly discussed in Chapter 34.

43.48 BALANOPOSTHITIS

In the stallion, inflammation of the glans penis (balanitis) and prepuce (posthitis) often occur together (balanoposthitis). Traumatic injury resulting in inflammation of the penis and prepuce has been discussed. Balanoposthitis may also be caused by dourine, EHV-3 infection (see Equine Coital Exanthema), miscellaneous bacteria, and parasites.[359,373,374,396,397]

43.49 EQUINE COITAL EXANTHEMA

Equine coital exanthema is caused by EHV-3.[398] The occurrence of neutralizing antibodies to EHV-3 primarily in horses of breeding age suggests that spread of this infection may be primarily by genital contact.[399] Typically an inapparently infected mare transmits the virus to a stallion at the time of breeding. The stallion then transmits the infection to other susceptible mares before developing clinical signs of the disease. Clinical signs in the stallion are sometimes more severe than those observed in the mare and may include systemic manifestations such as dullness, anorexia, and fever.[399] Vesicles up to 1.5 cm in diameter develop first on the penis and then on the prepuce 2 to 5 days later. The vesicles progress to circumscribed pustules with raised borders and depressed centers, which slough and ulcerate.[393,400] Scabs are seldom noted on penile lesions because they are rubbed off by extension and retraction of the penis during breeding.[400] Some affected stallions may refuse to breed mares, whereas others breed willingly, even while extensive penile lesions are present. Healing occurs in a few weeks, often leaving depigmented spots.[400]

Some immunity to the virus is acquired after infection, because reinfection without recurrence of clinically apparent disease is common. It is probable that the virus remains in the genitalia in a latent form.[373] Recurrent coital exanthema usually occurs in aged broodmares but may also occur in stallions.[400] In stallions, recurrence within the same breeding season is uncommon. The relationship between viral recrudescence and recurrent coital exanthema in the equine is unknown but may mimic that in human genital herpes infections.

Diagnosis usually can be made on the basis of the characteristic clinical signs. During the acute stage the virus can be isolated from swabs or scrapings taken from the edge of erosions. Inclusions in lesion specimens can be confirmed by using an electron microscope to visualize typical herpesvirus particles in fluid or tissue samples. Probably the most sensitive, specific, and accurate tool for the detection of EHV-3 is the PCR assay. Demonstration of antibody titers in serum may be useful in establishing time of exposure to the virus.[401]

Infection with EHV-3 is self-limiting.[373] Local treatment with antibiotic ointments will not speed healing but may minimize secondary bacterial infection and soreness.[400] Care should be taken to avoid iatrogenic transmission of

the infection (e.g., through contamination of sleeves, water, and examination or insemination equipment) to susceptible animals. Attending veterinarians may choose to refrain from breeding affected stallions until the lesions heal. One method that may be helpful in circumventing transmission of the infection while still breeding the stallion is to collect semen in an open-ended artificial vagina as soon as lesions are no longer painful. Collecting the semen as it directly exits the urethra reduces the chance of viral contamination from the penile and preputial lesions. It is imperative, however, to adhere to any breed registry restriction regarding artificial breeding.[361]

43.50 BACTERIAL INFECTIONS

43.50.1 STALLION

The external genitals of stallions harbor potentially pathogenic bacteria, fungi, and yeasts, yet balanoposthitis caused by bacterial agents is uncommon.[402–404] These organisms are usually considered to be surface contaminants, and the stallion is a lesionless carrier in most instances in which venereal transmission occurs.[378] Sperm motility, however, may sometimes be adversely affected by bacteria and their products in semen.[403] Offensive odors may occasionally be associated with heavy colonization of the penis and sheath with *Pseudomonas*, species or *Proteus*, species.[358] Documentation of a bacterial infection is dependent on serial isolation of a pathogen, preferably in large numbers and relatively pure culture.[404] A single isolation of *T. equigenitalis*, is considered diagnostic for CEM.[378] Samples for bacteriologic culture should be retrieved from the fossa glandis, free portion of the penile body, and folds of the external prepuce before washing of the genitals of a stallion presented to an estrual mare.[404]

If there is evidence of horizontal transmission of *Pseudomonas*, or *Klebsiella*, to mares, or if longevity of sperm is reduced in association with these organisms, the preferred method of management is to breed mares artificially with semen mixed with an antibiotic-containing semen extender.[405] Antibiotic selection is based on trials comparing extended semen with and without antibiotic. Extenders containing antibiotics that control the offending bacteria and permit maintenance of sperm motility are then used to breed mares.[406] Bacteria are usually not recovered after 5 to 30 minutes of incubation at room temperature.[403,405,406] Penicillin G (1000 to 1500 U/mL), streptomycin sulfate (1000 to 1500 mcg/mL), polymyxin B (100 to 1000 U/mL), reagent grade gentamicin sulfate (100 to 1000 mcg/mL), amikacin sulfate (100 to 1000 mcg/mL), or ticarcillin (100 to 1000 mcg/mL) is usually the most suitable antibiotic.[361] Gentamicin sulfate and amikacin sulfate should be buffered with 8.4% sodium bicarbonate solution to adjust pH to approximately neutral before they are mixed with semen extender. A suitable volume of extender can be infused into a mare's uterus immediately before cover when natural service is necessary.[405]

Colonization of the external genitals with *P. aeruginosa*, and *K. pneumoniae*, can be treated by thoroughly washing the penis and prepuce, including the fossa glandis and diverticulum, daily with an iodine-based surgical scrub. The genitals are then rinsed with copious quantities of tap water with dilute disinfectants added (10 mL of concentrated HCl per gallon of water for *Pseudomonas*, colonization, or 40 mL of 5.25% sodium hypochlorite bleach per gallon of water for *Klebsiella*, colonization).[407] Drying of the penis can be followed by generous application of 1% silver sulfadiazine cream. The procedure is repeated daily for 1 to 2 weeks and followed by serial cultures to determine if treatment was successful.[408] The clinician should be cognizant that

recolonization with these organisms may occur and that routine scrubbing and disinfection may predispose to infection of the genitals with potential pathogens by displacing commensal organisms.[402]

43.50.2 BULL

Balanoposthitis in the bull is caused by traumatic injury and infections. Whereas injury of the prepuce is more common, penile inflammation often accompanies the traumatic posthitis. A multitude of potentially pathogenic organisms inhabit the prepuce, and injuries predispose to infection particularly when deeper tissues are exposed. Pain and preputial discharge may be evident. Because of the presence of the many organisms in the preputial cavity, culture to identify a specific offending organism is likely to be misleading. When injury results in infection of the penis and prepuce, sexual rest in conjunction with local antibiotic treatment is indicated. Treatment should be performed as previously outlined for the penis and prepuce until inflammation is corrected.

Balanoposthitis unassociated with trauma has been associated with infections resulting from IBR-IPV, by tuberculosis, and by screwworm infestation.[358,373,374,409] Acute lesions associated with IBR-IPV infections are numerous small pustules that progress to ulcers and erosions in a few days. Purulent preputial discharge is present, and lesions may become confluent. The prepuce and penis may become quite inflamed and swollen. Healing is commonly spontaneous and rapid, beginning in 1 week and usually complete in 2 weeks. Severe cases may take longer to resolve.[409] Virus is shed from the prepuce for 2 weeks or longer, during which time venereal spread is possible. Sexual rest for 6 to 8 weeks has been recommended to prevent spread and to avoid abrasions that may aggravate inflammation.[358] Enlargement of the lymphoid follicles may be present, along with a seromucoid exudate for several weeks. Histologic changes include the transient appearance of eosinophilic intranuclear inclusions in degenerating epithelial cells.[373] Infusion of the preputial cavity daily may be of benefit in treatment, particularly in more severe cases. Vaccination with attenuated intranasal products has been reported as a method to prevent viral shedding into semen in bulls from AI studs.[358,410] The vaccine has been infused into the prepuce experimentally and did not result in viral shedding in the semen. Because persistence of herpesvirus in body tissues is a common occurrence, recurrence of viral shedding in semen after apparent recovery may be possible. Tuberculosis of the penis and sheath apparently has not been reported in the United States for some time. It is characterized by enlarged, granulomatous lesions on the glans penis, prepuce, and sigmoid flexure that are prone to hemorrhage. Penile lymph glands may abscess.[358]

43.51 Ram and Buck

Balanoposthitis (also called *pizzle rot, sheath rot*, and *ulcerative posthitis)*, commonly affects the penis and prepuce of intact and castrated male small ruminants.[367,368,411,412] The disease is discussed in Chapter 34.

43.52 PERSISTENT PENILE FRENULUM AND PENILE DEVIATIONS

43.52.1 BULL

43.52.1.1 Definition and Etiology

Phallocampsis, or deviation of the erect penis, is a relatively common condition in the bull. The most common cause of penile deviation is persistent penile frenulum.[358] Other types of penile deviations include spiral, ventral, and S-curved deviations.[357] Less commonly, preputial or penile injury may result in scar tissue formation that subsequently leads to deviation of the erect penis.[357]

When the penile frenulum persists, it remains connected to the ventral surface of the tip of the penis and the prepuce and causes the penis to bend ventrally during erection by preventing complete extension.[413] Copulatory ability is interfered with except in some of the Zebu-influenced breeds that are endowed with a plentiful prepuce.[357] Diagnosis is based on physical examination of the extended penis.

Because spiraling of the penis is thought to be a normal physiologic event that occurs in the vagina during ejaculation,[414] care should be taken in making this diagnosis. Bulls affected with penile deviations often have a history of no problems in mating cows for some time, occasionally for several breeding seasons. If such bulls have been closely observed, it may have been noted that the condition did not occur on every mating attempt, but the frequency of occurrence gradually increased until bulls might require numerous mounts to successfully intromit and breed a cow in estrus.[358] Penile deviations occur at full erection when the CCP is maximally distended with blood. Caution should be exercised in diagnosing this condition during erection stimulated by electroejaculation. Such erections are not considered to be entirely physiologic and frequently result in penile deviations in bulls that have no deviations under natural mating conditions. The spiral deviations that occur with use of the electroejaculator may be a result of tension exerted by the retractor penis muscles.[357] Diagnosis is best based on observing occurrence of the deviation frequently in natural mating situations.

The ventral or rainbow deviation of the penis is less common than the spiral deviation and is a result of the apical ligament being too thin to support the engorged, stretched distal end of the erect penis.[357] The ventral curvature may be quite pronounced, preventing affected bulls from directing and inserting the penis into the vagina of the female.

The least common of the spontaneous penile deviations is the S-shaped curvature. It primarily occurs in older bulls with an apical ligament that is short in relation to an excessively long penis.[254] Penile deviations that result from adhesions that developed from penile or preputial injury are diagnosed based on physical examination.

43.52.1.2 Treatment and Prognosis

Persistent penile frenulum is easily corrected by severing the persistent band. Owners of affected bulls should be advised of the probable genetic basis and therefore the undesirability of retaining such bulls for breeding.[357] Treatment of spiral and ventral deviations is surgical.[357]

43.53 TUMORS OF THE PENIS AND PREPUCE

43.53.1 STALLION

43.53.1.1 Clinical Signs and Differential Diagnoses

The most common neoplasm of stallion genitalia is SCC. Generally, it is of low malignancy.[357,415] The tumor usually involves the glans penis but may also involve the shaft of the penis and prepuce and produce a fetid discharge.[373,374] Large tumors may ulcerate and bleed, resulting in hemospermia. Carcinomas may resemble *Habronema*, granulomas, which are more common and are diagnosed by histologic examination of affected tissue.[358,361] Carcinomas are usually well differentiated and surrounded by eosinophils. Necrosis and calcification may occur, but parasite larvae are usually not present[373] unless secondary habronemiasis has occurred from flies feeding on the ulcerated tissue. Carcinomas may extend into the CCP or may metastasize to the inguinal lymph nodes or other abdominal or thoracic organs.[373] The superficial inguinal lymph nodes lie midway between the prepuce and external inguinal ring; secondary tumors in this region often grow rapidly and develop necrotic centers with purulent sinuses that must be differentiated from bastard strangles.[357]

1475

1476

Tumors encountered much less frequently include melanoma, papilloma, angioma, lymphosarcoma, and sarcoid. Melanoma is a common equine tumor, especially of grey horses,[369] and occasionally involves the penis and prepuce[357,359,416] (see Chapter 40). Genital papillomas are rare in stallions but may occur on the glans or shaft of the penis. The lesions appear as multiple proliferative cutaneous growths and may become friable and result in hemorrhage during erection and ejaculation.[361] The lesions are generally thought to be caused by a papilloma virus,[417,418] and papilloma virus antigens have been found in cutaneous and genital papillomas.[418] Angiomas and lymphosarcomas have occasionally been reported on the genitals of stallions.[359] Sarcoids may involve the skin of the prepuce or scrotum[357,416] (see Chapter 40).

43.53.1.2 Treatment and Prognosis

When SCCs are relatively small and noninvasively attached to the skin, neoplasms may be successfully treated by cryosurgery or hyperthermia.[419] Hyperthermic treatment (50° C for 1 to 2 minutes) appears to be most successful for SCC when lesions are small (less than approximately 2 cm). If the tumor is extensive but superficial, cryosurgery may be attempted after the tumor is debulked and hemorrhage controlled. The remaining base of the tumor is then frozen and thawed twice; healing occurs as necrotic tissue is sloughed. Successful treatment of small lesions has been reported with topical application of 5-fluorouracil.[420] If removal of tumors is unsuccessful or if neoplasia is extensive, penile amputation may be necessary.[357,421] If superficial inguinal lymph nodes are involved, euthanasia may be required.[357]

In contrast to nongenital squamous papillomas, genital forms generally are quite refractory to treatment.[361] Surgical removal and autogenous vaccine administration have been tried to treat fibropapilloma of the penis of two stallions but did not effect a cure.[388]

43.53.2 BULL

43.53.2.1 Definition and Etiology

Fibropapilloma is the only tumor that frequently invades the bovine penis or prepuce.[373,374] The tumor may be single or multiple and usually affects young bulls. The cause is thought to be a papilloma virus antigenically similar to the virus that causes cutaneous papillomatosis in cattle.[422] Frequent mounting among young bulls is thought to result in damage to epithelial surfaces of the penis and prepuce that serves as a route of entry for the virus.[357,358]

43.53.2.2 Clinical Signs

Small papillomas may be discovered during routine breeding soundness evaluations, but many become larger before they are discovered. Large fibropapillomas may prevent withdrawal of the penis into the preputial cavity. Fibropapillomas are pedunculated and attached at a narrow base in early cases. The surface becomes cauliflower-like and friable; hemorrhage is easily induced.

43.53.2.3 Treatment and Prognosis

Many fibropapillomas regress spontaneously within a few months. Regression may be more likely in bulls approaching 2 years of age and usually occurs within 4 months of the appearance on the penis.[422,423] Several vaccines, including autogenous preparations, have been used for treatment, but vaccines may be more successful for prophylaxis.[358] Frequently, surgical removal is indicated, but the fibropapillomas may recur. If only superficial attachment is present, surgical removal is easily accomplished. Catheterization of the distal urethra before surgery is helpful in identifying its location to avoid injury. If attachment has become extensive and sessile, amputation of a portion of the distal penis may be necessary.[357] Housing of young replacement bulls in individual pens, if possible, is recommended as a method to reduce the incidence of penile fibropapillomas.

43.54 PARASITIC INFESTATIONS OF THE PENIS AND PREPUCE IN STALLIONS

43.54.1 Definition and Etiology

Habronema muscae, Habronema microstoma, and *Draschia megastoma*, larvae commonly invade the urethral process, glans penis, and preputial ring of stallions.[357,369] Other terms for this condition are *genital bursatti*, and *summer sores*.,[373]

43.54.2 Clinical Signs

Shallow irritations progress to irregular 1- to 3-cm granulomatous growths that may involve the entire circumference of the urethral process.[358] Lesions are friable and bleed when manipulated. Stretching of the infected urethral process during penile engorgement and ejaculation may result in hemospermia.[361] Pruritus

associated with the lesions may be intense. Frequent micturition and dysuria may resemble urine spraying that accompanies accumulation of smegma in the urethral diverticulum ("bean"). Lesions subside during the colder months in northern areas but usually reappear and increase in size during subsequent warm weather.[358] Diagnosis is made by seeing yellowish granules (calcified larvae) in the lesion and by microscopic identification of larvae.[369]

43.54.3 Treatment and Prognosis

See Chapter 40 for treatment and prognosis information.

43.55 HEMOSPERMIA

Hemospermia, refers to contamination of ejaculates with blood. Stallions with overt hemorrhage into ejaculates are subfertile. Erythrocytes rather than serum have been implicated for the marked depression of fertility, although the precise factor(s) involved are not known.[389] A small amount of sanguineous contamination is compatible with fertility, especially if the semen is quickly diluted with a suitable extender before insemination. A disproportionate number of leukocytes to erythrocytes suggests infection of the internal genital organs. Specific causes of hemospermia include lacerations of the penis, cutaneous habronemiasis, urethritis, urethral lacerations, and infection or inflammation of the accessory genital glands,[361] which are discussed elsewhere in this chapter.

43.56 UROSPERMIA (URINATION DURING EJACULATION)

43.56.1 Definition and Etiology

Urospermia is an uncommon but perplexing disorder of breeding stallions. Affected stallions generally exhibit normal libido and mating ability, but semen becomes contaminated with urine during the ejaculatory process. The problem may be incessant or unpredictably intermittent; urination can occur at any time or continuously during ejaculation. The amount of urine ranges up to 250 mL or more.[361] 1476 1477

The underlying cause(s) of urospermia is speculative. Closure of the bladder sphincter and seminal emission are controlled by the α-adrenergic sympathetic nervous system, and a disturbance in this pathway might contribute to urospermia.[424] Similarly, neuropathies that result in bladder paralysis (e.g., cauda equina neuritis or nerve damage secondary to EHV-3 infection or sorghum or Sudan grass poisoning) can create urinary incontinence that permits voiding during ejaculation. Most stallions with urospermia do not exhibit signs of a neurologic deficit.[361]

43.56.2 Clinical Signs and Differential Diagnoses

Gross contamination of ejaculated semen with urine is easily detected by its color and odor. Contamination with significant quantities of urine adversely affects sperm motility and fertilizing capacity. Elevated concentrations (relative to serum levels) of urea nitrogen or creatinine in semen document presence of urine in the ejaculate.[361,425]

43.56.3 Treatment and Prognosis

Treatment options for urospermia vary, can be arduous, and are often unrewarding. Delay of semen collection (or breeding) until immediately after the stallion has voided urine may be a helpful management policy. Urination can be stimulated by administration of a diuretic drug (e.g., furosemide). Stallions may also void urine when provided access to feces of another stallion. Some stallions can be trained to urinate on command. Alternatively, the bladder can be catheterized to aid evacuation of urine before breeding, but urethritis or cystitis may result from routine use of this procedure. Fractionation of ejaculates using an open-ended artificial vagina can be used alone or in combination with any of the above measures. When an open-ended artificial vagina is used, only the first three jets of the ejaculate are collected. These jets contain a majority of the spermatozoa in the ejaculate, and urination may not occur until the end of the ejaculatory process.[426] Dilution of urine-contaminated semen in extender can restore sperm motility. Semen may be centrifuged after initial dilution, and the sperm pellet resuspended in extender before insemination[361]; however, centrifugation to remove urine may not provide a significant advantage over dilution in extender.[426]

Pharmacologic agents such as bethanechol chloride or flavoxate hydrochloride have been used in an attempt to correct urospermia but usually without success.[361] α-Sympathomimetic drugs have sometimes been used successfully to prevent retrograde ejaculation in men, but their use has not been critically studied in stallions.[427] Oral administration of imipramine (100 to 500 mg twice daily) has reportedly been useful for controlling urospermia in stallions, presumably by enhancing contractility of the bladder neck during emission.[424]

43.57 INFERTILITY CAUSED BY DISEASES OF THE SCROTUM AND TESTES

43.57.1 SCROTAL INJURY, HYDROCELE, AND HEMATOCELE

43.57.1.1 Definition and Etiology

Trauma to the scrotum can result in excoriation, lacerations, hemorrhage, and edema.[358,373] Systemic diseases such as hepatic disease and EIA may result in scrotal edema.[358,378] Suppurative inflammation may develop as an extension of scrotal injury.[358] Adhesions often develop between the visceral and parietal tunics when inflammation, infection, or hemorrhage occurs.[374] Adhesions are usually thin fibrous strands that become thickened over time. In such cases the testis and its tunics are not freely movable within the scrotum.[373]

Hydrocele is an accumulation of serous fluid within the vaginal tunic.[374] Ascites, anasarca, or local lymphedema may contribute to hydrocele because the vaginal tunic communicates with the peritoneal cavity.[373] Accumulation of a significant volume of fluid around the testis may cause thermal degeneration and a decline in seminal quality.[428]

Hematocele occurs when trauma to the scrotum results in accumulation of blood within the testicular tunics.[374] Scrotal damage initially accompanies hematocele. Thermal degeneration of the testes follows, and a thick fibrous capsule encompasses the testis after the blood clot organizes.[429]

43.57.1.2

Clinical Signs and Differential Diagnoses

Diagnosis of scrotal injury, hydrocele, and hematocele is made by physical and ultrasonic examination of the scrotum. Testes remain freely movable within the scrotum if hydrocele is present. Ultrasonographic examination reveals variable amounts of anechoic fluid surrounding the testes and epididymides, which are easy to visualize because of their echoic nature against the fluid background. With hematocele, evidence of trauma is often present, with thickening of the scrotal skin. Blood surrounding the testis and epididymides becomes progressively more echogenic over time as the clot organizes.[361,430] Extensive edema of the scrotal fascia next to the tunica dartos may be difficult to differentiate ultrasonographically from hematocele. Abdominal paracentesis is helpful in eliminating ascites or peritonitis as a cause of hydrocele. Palpation per rectum of stallions and bulls may occasionally reveal that the internal inguinal rings are enlarged, readily permitting fluid transfer into the vaginal cavity.

An aseptic tap is useful to identify the character of this fluid and must be performed with care not to contaminate or penetrate the testis or its visceral vaginal tunic.[429] A modified transudate of low cellularity is typical of fluid drained from a hydrocele.[431] Fluid usually returns after drainage unless the initiating cause is corrected.[361]

43.57.1.3

Treatment and Prognosis

Acute scrotal injury is treated with cold water or ice application to reduce edema (see earlier discussion on penile and preputial injuries). Lacerations and abrasions should be treated with topical antibiotic ointments. Systemic antiinflammatory drugs and antibiotics may reduce swelling, control infection, and prevent abscess formation.[361,429]

Scrotal thickening usually results in elevation of testicular temperature, causing degeneration and atrophy similar to that seen with experimental scrotal insulation.[432,433] Semen quality quickly deteriorates, and a rapid reduction in numbers and motility of spermatozoa occurs with a concurrent increase in morphologic abnormalities of spermatozoa.[358,373,434] If swelling and edema resolve and adhesions do not develop among the testes, tunics, and scrotum, spermatozoa may gradually reappear in the ejaculate by 1 to 2 months after injury, but 4 to 5 months may be required for testes to return to normal size and sperm production.[360] One or both testes may remain atrophic and become firm because of fibrosis and loss of tubules. If only one testis is atrophied, the normal testis may eventually hypertrophy.

If hemorrhage occurs within the scrotum or testicular tunics, the prognosis for return of testicular function is poor. In unilateral cases, surgical removal of the clot and affected testis may minimize damage and speed recovery of the remaining testis.[435,436] Hydrocele is managed by correcting the underlying cause of fluid accumulation such as peritonitis or ascites.[429] Exercise may aid in control of fluid accumulation in some horses. Some stallions and bulls with persistent minor fluid accumulations within the tunics may continue to produce sufficient normal spermatozoa.[358] Permanent testicular degeneration may result in cases with extensive fluid accumulation that are unresponsive to therapy. If the condition is unilateral, removal of the affected testis may permit the animal to remain in service.[431] Because hydrocele and associated impairment of spermatogenesis may be transient (2 to 6 months),[428] caution should be exercised in recommending castration or culling of affected animals until demonstration that the disorder is long-standing.

43.58 SCROTAL DERMATITIS AND ABSCESS

The scrotal skin is delicate and vulnerable to dermatitis. Causes include nonspecific environmental contaminants, bacteria, fungi, parasites, and frostbite.* Scrotal abscesses are not uncommon in small ruminants and are due to shearing injuries and penetrating wounds.[367] Treatment is directed toward removing the affected testis. Bulls affected by frostbite should be provided a warm and dry environment.[437] Systemic and local antibiotics may be indicated. Abscesses should be drained. Thermal degeneration of the testes may follow dermatitis and may be temporary or permanent.[358] Semen quality should be evaluated at periodic intervals after skin lesions have resolved to gauge prognosis for improvement and return to fertility.

* References 367, 369, 373, 374, 434, 437.

43.59 TESTICULAR APLASIA AND HYPOPLASIA

43.59.1 Definition and Etiology

Complete absence (aplasia) of one or both testes is rare and usually occurs in conjunction with anomalous development of other organs.[358,438] Testicular hypoplasia may be unilateral or bilateral and affects both scrotal and abdominal testes.[374] Testicular hypoplasia is thought to result from failure of germ cells to multiply in the gonad.[258] Causes of testicular hypoplasia may include transplacental infections and intoxications, zinc deficiency, hormonal insufficiency, impaired testicular descent, abnormal karyotype, and vascular disturbances.† Exogenous administration of hormones to prepubertal males can result in testicular hypoplasia. Testicular size of adult stallions is reduced after prolonged administration of exogenous steroids.[440–442] Scrotal circumference is diminished in bulls implanted with zeranol.[443]

† References 368, 373, 374, 434, 439.

43.59.2 Clinical Signs and Differential Diagnoses

Hypoplastic testes are usually smaller than normal, but they occasionally are normal in size.[373] The scrotal circumference of beef bulls should be at least 32 cm at 12 months of age.[444–446] Stallions 3 years of age should have a scrotal width greater than 8 cm.[378,447] Yearling rams with a scrotal circumference of less than 30 cm and mature rams with a scrotal circumference of less than 32 cm are not recommended for breeding.[448] The texture of affected testes varies from normal to soft in mild or moderate hypoplasia. Severely affected small testes are firm because of the relatively increased amount of stromal connective tissue.[374]

Depending on the number of seminiferous tubules affected, ejaculates from males with testicular hypoplasia may be azoospermic or may contain a low concentration of spermatozoa with numerous morphologic defects.[358] Round spermatogenic cells may also appear in ejaculates, along with giant and medusa cells.[374]

43.59.3 Treatment and Prognosis

No successful treatment is available for severe hypoplasia. The useful breeding life of males with testicular hypoplasia may be shortened because affected bulls are thought to be predisposed to early testicular

degeneration.[444] Because of the value of some individuals, particularly stallions, owners may elect to breed males with small testes. Effective management of such stallions is based on breeding a book of mares limited by the number of normal, motile spermatozoa present in ejaculates.

43.60 CRYPTORCHIDISM

43.60.1 Definition and Etiology

Incomplete or abnormal testicular descent is thought to be a genetic abnormality.[358,368,374] The inheritance pattern in horses is thought to be dominant,[449] although studies of offspring of some cryptorchid stallions suggest that inheritance of the condition may be multifactorial.[450] The relative risk for equine cryptorchism also appears to be influenced by breed.[451] Other modes of inheritance have been suggested from studies of offspring of cryptorchid rams, bucks, and bulls. These include a recessive gene with incomplete penetrance in Angora goats,[452] a dominant gene with variable expressivity in Hereford cattle,[453] and either an autosomal recessive gene or a dominant gene with incomplete penetrance in inbred sheep.[454]

Testes originate near the kidney and migrate to the superficial inguinal rings before descending into the scrotum; the epididymis precedes the testis in descent. Retained testes are located at some point along the path of migration.[373] Ectopic testes not associated with cryptorchidism may be found under the skin of the ventral caudal abdomen or elsewhere in bulls.[357,374]

43.60.2 Clinical Signs and Differential Diagnoses

The majority of cases of cryptorchidism in stallions are unilateral.[455] Although testicular descent can occur in horses up to 2 years of age, the testes are normally descended at birth in large animals.[456] Testes are readily palpated in the scrotum of colts at 30 days of age.[358,359] Spermatogenesis is inhibited in the abdominal testis because of the elevated temperature within the abdomen. The interstitial cells remain active and secrete testosterone,[359,373,374] enabling even bilateral cryptorchids to maintain libido and copulatory activity. The descended testis may be hypertrophic[373]; unilateral cryptorchids are fertile but are not considered sound breeders.[358,457]

Deep palpation of the superficial inguinal rings may reveal the testis in the canal (“high flankers”). If the testis is not located in the inguinal canal, transrectal palpation or ultrasonography can be performed in stallions and bulls in an attempt to locate a testis or to detect the vas or epididymis entering the superficial inguinal ring, thereby providing evidence of descent into the inguinal canal.[458]

43.60.3 Clinical Pathology

Equine cryptorchids have high basal concentrations of testosterone (usually >100 pg/mL) and respond to hCG administration (10,000 to 12,000 IU IV) with a significant elevation of circulating testosterone within 30 to 60 minutes if testicular tissue is present. Geldings and “false rigs” (geldings with malelike behavior) have low basal concentrations of testosterone (<40 pg/mL) and do not respond to hCG stimulation. Stallion testes contain a high concentration of conjugated estrogens, and a single measurement of high plasma conjugated estrogens

1478
1479

(>400 ng/mL) is reported to be almost as reliable in diagnosing cryptorchidism as hCG stimulation.[459,460] In some ruminants, measurement of testosterone concentrations before and after administration of hCG has also proved helpful in identifying cryptorchidism.[461]

43.60.4 Treatment and Prognosis

Stimulation of testicular descent with repeated injections of GnRH, sometimes combined with hCG or acupuncture, has been attempted, but the success has not been critically evaluated. Surgical removal of the abdominal and scrotal testes is indicated.[357] Surgical placement of the retained testis into the scrotum is not considered an ethical procedure.

43.61 TESTICULAR DEGENERATION

43.61.1 Definition and Etiology

Testicular degeneration is an acquired condition with multiple causes.[462] Infections or traumatic orchitis may progress to permanent degeneration. Degeneration may be associated with thermal factors after elevation of body temperature by systemic infections; prolonged increase or decrease in ambient temperature; scrotal insulation from edema, dermatitis, scrotal hernias, or hemorrhage; or abnormal conformation resulting in an incompetent heat exchange system.* Degeneration results when testicular vasculature becomes occluded in torsion of the spermatic cord.[466] Obstruction of the proximal epididymis and malformation of the efferent tubules results in degeneration caused by pressure within the seminiferous tubules.[434] Various chemicals and ionizing radiation are capable of inducing testicular degeneration.[373] Administration of steroid hormones may induce testicular degeneration by inhibiting secretion of gonadotropins.[428,467,468] Gradual degeneration also occurs with increasing age.[469]

* References 359, 373, 432, 434, 437, 463–465, 478.

43.61.2 Clinical Signs and Differential Diagnoses

Diagnosis of testicular degeneration is based on physical examination and semen evaluation. Testes are typically thought to be small, but they may be normal size. Semen examination reveals a low concentration of spermatozoa, a decreased number of spermatozoa in the ejaculate, and a high percentage of spermatozoa with morphologic defects, sometimes with premature (round) germ cells.[357] Without a history of normal testis size and function before atrophy, differentiation from testicular hypoplasia is usually not possible.[374,378] Discrepancies between testicular size (measured by scrotal width in stallions and scrotal circumference in ruminants) and daily sperm output may indicate testicular degeneration.[443,446,470,471]

43.61.3 Clinical Pathology

The measurement of plasma hormone concentrations may be helpful in establishing a diagnosis of testicular degeneration in large animals. However, the relationship between the concentrations of various hormones and the parameters of testicular function appears to be quite variable. Measurements of hormone concentrations in subfertile stallions have demonstrated that serum gonadotropins can be abnormally low or high.[472] Hormonal

criteria for confirming testicular degeneration in stallions typically include low concentrations of testosterone, with concurrent low LH concentrations in early cases of degeneration, or with high FSH and low estradiol concentrations in cases of chronic (or irreversible) testicular degeneration.[360] Less is known concerning hormone concentrations in other large animal species with testicular dysfunction. In one study, plasma testosterone concentrations were lower in young beef bulls with testicular degeneration than in a similar group of normospermic bulls; however, patterns of secretion and plasma concentrations of LH and FSH were not significantly different between the two groups.[446] Scrotal insulation of rams resulted in an increase in plasma FSH concentrations and a decrease in plasma testosterone concentrations within 1 to 4 weeks.[473]

Testicular biopsy can confirm degeneration.[474] Excision of an amount of tissue sufficient for evaluation often results in hemorrhage, pressure degeneration, and necrosis.[358] Therefore testicular biopsy is usually undertaken only as a final recourse. However, testicular biopsy in the stallion appears to be a relatively safe procedure.[475]

43.61.4 Treatment and Prognosis

Once testicular degeneration has occurred, treatment is usually of no benefit.[358] However, any factors that might contribute to testicular degeneration (such as febrile conditions or systemic illness) should be corrected. Treatment of injuries of the scrotum and its contents was described earlier in this chapter.

Recent findings regarding variations in serum hormone concentrations in subfertile stallions have stimulated an interest in gonadotropin replacement therapy, including the use of GnRH. Although the hypothalamic-pituitary-testicular (HPT) axis of the stallion is remarkably refractory to GnRH-induced downregulation compared with other domestic species,[476] few controlled studies have evaluated the effectiveness of GnRH therapy. In one study, pulsatile or constant administration of GnRH for 20 weeks did not promote testicular growth or alter spermatozoa output in reproductively sound or unsound stallions.[477]

In some cases, degeneration is temporary, and improved semen quality is evident after 2 to 5 months. The prognosis for an animal recovering its fertility and the economic losses the client will sustain from treatment and decreased production must be considered when deciding whether treatment of testicular degeneration is warranted.

43.62 ORCHITIS

43.62.1 Definition and Etiology

Orchitis is most commonly caused by infection or trauma. Bacterial infections may develop hematogenously, or occasionally by retrograde movement from infected accessory sex glands.[374] Extension of infection to the testes from periorchitis or epididymitis also occurs.[434] Testicular enlargement is due to edema that accompanies the inflammatory reaction. Contusion and inflammation of the testes occur in racing stallions, particularly standardbreds.[359] *S. zooepidemicus*, is commonly isolated from infectious orchitis in stallions.[360] In bulls, infectious orchitis is caused by *B. abortus, M. tuberculosis, A. pyogenes, Nocardia farcinica*, bovine herpesvirus 3 (IBR-IPV), and other miscellaneous organisms.[358,373,374,434] Epididymoorchitis in rams may be associated with *B. ovis*, or *Actinobacillus seminis*, and *Actinobacillus*,-like organisms.[368]

43.62.2 Clinical Signs and Differential Diagnoses

Acutely orchitic testes are hot, swollen, and painful. The swollen testis is turgid because of restriction by the tunica albuginea. Edema of the testicular parenchyma, and concurrent presence of periorchitis or epididymitis, may be detectable by ultrasound examination. Increased testicular temperature, congestion, and interference with circulation lead to ischemia and infarction. Abscesses sometimes develop, occasionally culminating in purulent liquefaction of testicular parenchyma. Testicular atrophy and fibrosis follow as the condition becomes chronic.[373,374]

1479
1480

Acutely affected animals may refuse to mate. Ejaculates may contain numerous white blood cells. Variable mineralization of seminiferous tubules can occur as a chronic change. Decreased sperm motility and increased sperm morphologic abnormalities are evident. Standardbreds affected by acute orchitis may switch from a trot to a pace, whereas thoroughbreds may suddenly develop a hopping gait.[358]

43.62.3 Treatment and Prognosis

Treatment consists of scrotal cryotherapy and systemic administration of antiinflammatory drugs. Bacterial orchitis is treated with antibiotics chosen by semen culture and in vitro sensitivity. Antibiotic therapy should continue for 1 to 2 weeks beyond resolution of testicular swelling and pain.[361] Testicular atrophy and sterility are common sequelae to orchitis.[359] Changes in the testes, including precise measurements of in situ testis size, are followed by sequential ultrasound examinations or caliper measurements. Serial semen analyses over a period of several months allow the clinician to monitor response to treatment and return of testes to normal production of spermatozoa.

43.62.4 Prevention and Control

Support devices may aid in preventing recurrence of traumatic orchitis in racehorses. With *Brucella*, or *Actinobacillus*, orchitis in sheep, the presence of subclinical carriers in the flock must be considered.[411]

43.63 TESTICULAR NEOPLASIA

43.63.1 Definition and Etiology

Primary testicular tumors are uncommon in large animals but may be slightly more frequent in older bulls than in stallions or rams. Testicular tumors originate from the interstitial (Leydig) cells, Sertoli cells, and the germinal epithelium. Testicular teratomas and lipomas of the testicular surface and lymphosarcoma also occur.[*] Although the incidence of testicular tumors is relatively greater in retained than in scrotal testes in dogs, this predisposition has not been confirmed in large animals, perhaps because most are castrated at an early age before the time of usual onset of testicular neoplasia. Retained testes in the horse, however, are thought to be more prone to neoplasia. Teratomas in particular are found more commonly in cryptorchid than in scrotal testes, probably because they are embryonal in origin and their size prevents migration of the testis into the scrotum.[373,374]

Seminomas are the most common primary testicular tumor in the descended testes of adult stallions, with the majority occurring in stallions over 10 years of age.[373,374,481] Seminomas are not hormonally active and are usually benign but may be malignant and invade inguinal and abdominal tissues.[361,482] Seminomas are rare and benign in bulls and are rarely seen in aged rams, where they are occasionally highly malignant.[373] The tumor arises from the germinal epithelium and occurs in retained and scrotal testes; these tumors grow very rapidly.[358,373]

Interstitial (Leydig) cell tumors have been reported in stallions and bulls[434] and can have a negative impact on semen quality and fertility.[483,484] Most do not produce androgenic hormones.[373] They may be single or multiple in one or both testes and are commonly 1 to 2 cm in diameter.[373]

Sertoli cell tumors are reported in horses, cattle, and sheep, but they are rare. Although metastasis is uncommon, extension of neoplastic tissue into the testicular vein and lymphatics can result in hydrocele.[373] Because of the importance of Sertoli cells in spermatogenesis, these tumors are likely to exert an adverse effect on semen quality and fertility. Tumors in newborn or young calves may be a result of impaired embryogenesis.[373,380]

Teratomas are usually benign tumors commonly found in cryptorchid testes of horses.[478,485] They are rare in other large domestic species. The tumors are often cystic and vary in diameter from 10 to 25 cm or more. Structures present in teratomas arise from all three embryonic layers and include hair, nervous tissue, salivary glands, adipose tissue, cartilage, and bone.[373,374]

* References 373, 374, 415, 434, 478–480.

43.63.2 Clinical Signs and Differential Diagnoses

Neoplastic testes are often larger than normal, with an affected scrotal testis often twice the size of the unaffected testis, especially in cases of seminoma. Abdominally located testicular tumors can be quite large. Neoplastic testes, particularly seminomas, are typically irregular and firm. Swelling may extend into the spermatic cord, and pain may be present that interferes with breeding or is evident on palpation. Ultrasonographically, testicular tumors tend to appear as discrete, well-circumscribed hypoechoic areas within the usually homogenous testicular parenchyma.[361,430] However, seminomas may involve so much of the testis at the time of diagnosis that differentiation between neoplastic and normal tissue can be difficult.

Swelling of the affected testis may interfere with thermoregulation of the contralateral testis, resulting in decreased sperm production. Semen examination, however, may reveal seminal parameters to be within normal limits, and fertility may be acceptable. A significant amount of normal testicular parenchyma may remain covering the tumor, and living spermatozoa may or may not be present in the epididymis on the same side.[358,373,374,486]

43.63.3 Treatment and Prognosis

Testicular tumors should be surgically removed. Although metastasis is uncommon, early identification and removal of unilateral tumors prevents spread to other tissues. If semen quality is satisfactory in seasonal breeders, removal may be delayed until the breeding season is completed to avoid the transient decrease in

semen quality associated with postsurgical swelling. If neoplasia is bilateral, surgical removal may be delayed until semen quality deteriorates sufficiently to negate the use of the animal for breeding.[361]

43.64 INFERTILITY CAUSED BY DISEASES OF THE SPERMATIC CORD

43.64.1 TORSION OF THE SPERMATIC CORD

43.64.1.1 Definition and Etiology

Torsion of the spermatic cord occurs more commonly in stallions than in other large animals because of the horizontal position of the testes within the scrotum. Torsions may be transient or permanent and typically are of 180 to 360 degrees, but rotations may be greater.[381] Abnormal elongation of the caudal ligament of the epididymis (scrotal ligament), the proper ligament of the testis, or an excessively long mesorchium may encourage spermatic cord torsion.[466,487]

43.64.1.2 Clinical Signs and Differential Diagnoses

Torsion of the spermatic cord occurs in degrees that vary from those producing no pain or abnormality of semen to those involving vascular obstruction and acute colic.[359] Torsion is often a transient condition that does not interfere with testicular function or cause pain.[457] In those cases the testis is usually rotated 180 degrees or less. If torsion is of sufficient degree to result in vascular compromise, acute pain results.[358,359,487,488] Diagnosis of torsion of the spermatic cord is aided when displacement of the tail of the epididymis and scrotal ligament is evident on palpation. The head of the epididymis is normally located craniodorsal to the testis and the tail lies caudally, where it is attached to the testis by the proper ligament. The tail of the epididymis is most readily palpable, and its location is helpful in determining the degree of rotation. Torsions of 360 degrees or greater generally cause clinical signs that must be differentiated from strangulation of herniated contents into the scrotum. The primary method used to differentiate between the two conditions is palpation per rectum of the superficial inguinal ring to identify if herniation is present.[361]

Clinical signs of vascular impairment with spermatic cord torsion include abdominal discomfort, elevated heart and respiratory rates, unilateral swelling and edema of the scrotum, and increased testicular temperature.[361] Affected testes are painful and quickly become soft and friable.[358,359,487,488]

43.64.1.3 Treatment and Prognosis

Manual correction of spermatic cord torsion is sometimes possible, but recurrence is likely. To attempt manual correction, the horse is sedated and the testis is rotated in the direction opposite the torsion. Both hands are used to reposition the scrotum as the testis and its tunics are rotated.[359] Surgical correction is indicated if manual correction is not possible.[361] Nonsteroidal antiinflammatory drugs and analgesics may be administered to control pain.

The rapidity with which correction must occur is unknown; human testes may be salvageable if torsion is corrected within 6 hours. If hemorrhage or necrosis of the testis is evident, removal is indicated because the

contralateral testis may become permanently damaged. The mechanism of the damage is probably immunologic, resulting from antibodies to spermatozoa liberated as a result of ischemia.[489]

43.64.2 VARICOCELE

43.64.2.1 Definition and Etiology

Varicoceles are abnormally distended and tortuous veins of the pampiniform plexus.[411,465] Varicoceles are most often recognized in rams, in which dilations in vessels may reach 15 cm and discourage movement and libido.[454] The incidence of varicoceles increases significantly with age, reaching approximately 2% in rams 3 years of age and older.[438] Varicoceles have been reported infrequently in stallions.[361]

Varicoceles may result from insufficiency of veins draining the testis or a deficiency of the fascia and connective tissue surrounding those veins that allows backflow and stasis of blood in the vessels.[373] Infertility associated with varicocele is thought to result from disturbance of the local thermoregulatory mechanism, causing increased testicular temperature and subsequent disturbance in spermatogenesis.[361] Concomitant atrophy of the testis is common in rams.[438] Bilateral varicoceles and atrophied testes have been reported in the ram.[490]

43.64.2.2 Clinical Signs and Differential Diagnoses

Diagnosis of varicocele is made by palpating the dilated tortuous veins (“bag of worms”) within the spermatic cord.[358,411] Confirmation of the varicocele has been accomplished by ultrasonographic examination in stallions. Large echolucent areas in the venous plexus of the spermatic cord, sometimes with concurrent distention of the central vein of the testis, are described as the identifying features.[430] The ultrasonographic appearance of a suspected varicocele can be compared with the structures of an uninvolved contralateral testis and spermatic cord or those of an unaffected animal.

Thombosis of the varicocele can occur.[358,373] The large, organizing laminated thrombi can be mistaken as *Corynebacterium pseudotuberculosis*, abscesses in the scrotal fascia of rams.[373] Varicoceles might also be mistaken for sperm granulomas of the caput epididymis. Unless thrombosis has occurred, varicoceles are typically fluxuant and soft and fail to elicit pain when palpated.

43.64.2.3 Treatment and Prognosis

Surgical removal of varicocele has improved semen quality and fertility of some human patients but has not been reported in large animals. Thrombosis of a varicocele necessitates unilateral castration, with transection of the spermatic cord proximal to the thrombus.[357] Castration is also recommended for rams because of potential heritability risks.[454]

43.65 INFERTILITY CAUSED BY DISEASES OF THE EPIDIDYMIS AND ACCESSORY SEX GLANDS

43.65.1 EPIDIDYMITIS

43.65.1.1 Definition and Etiology

Epididymitis is caused by infection or trauma and may occur separately but is commonly secondary to orchitis or infection of the accessory sex glands.[373,374,491] The tail of the epididymis is commonly involved, but the head and body may be affected. *S. zooepidemicus*, is commonly isolated from equine epididymitis, although a number of other miscellaneous organisms, including *Proteus mirabilis*, have been incriminated.[358,492] In bulls, *B. abortus, A. seminis, A. pyogenes*, and other miscellaneous organisms cause epididymitis.[373,374,491] In mature rams the disease is commonly associated with *B. ovis*, whereas in ram lambs organisms from the *Actinobacillus, Haemophilus, Histophilus*, and *Corynebacterium*, groups are prevalent.[411,493] Routes of infection have been postulated to be hematogenous, venereal, or ascending from genitourinary passages, similar to routes of infection proposed for orchitis.[358,373] All routes of infection are likely to occur to some degree, depending on the pathogen and species involved. In an interesting study performed in yearling rams, conjunctival inoculation of *B. ovis*, culminated primarily in localized infections of the reproductive tract, which tended to first result in lesions of the distal tail of the epididymis.[494] Injuries, such as penetrating wounds, may also result in epididymitis.

43.65.1.2 Clinical Signs and Differential Diagnoses

Diagnosis of epididymitis is based on detection of clinical signs that include pain when irregular swellings of the epididymis are palpated, changes in shape and texture of the organ, adhesions between the epididymis and scrotal tunics, and enlargement of the tail of the epididymis.[358,361,411] The course of epididymitis varies from acute swelling and edema to chronic abscesses, periorchitis, and fibrosis.[373,374] Granulomas may develop if sperm escape into surrounding tissue.[438,491,495] In rams, epididymal lesions may be palpable along the entire length. Abnormal sperm morphology (especially detached heads) and leukocytes in the ejaculate may be seen before lesions are palpable.[496]

1481

1482

Animals affected with the *Actinobacillus, Histophilus*, and *Haemophilus*, groups of organisms may acquire an epididymoorchitis syndrome.[411,497] Affected rams are usually less than 1 year of age. They may be subclinical carriers or acutely ill with pyrexia, depression, pain as evidenced by an arched back, and unilateral or bilateral swelling and tenderness of the scrotal contents. If these animals recover from the acute phase, the disease may become chronic and is characterized by an enlarged, firm, and often irregular epididymis; palpable adhesions of portions of the epididymis to the testis and vaginal tunics; atrophic testes; abscess formation; and draining fistulas to the scrotal surface. Ultrasonographic examination of the epididymis may reveal dilated ducts, fluid accumulation around the tail of the epididymis, and cystic areas within the epididymis that contain purulent material.[361,430]

43.65.1.3 Clinical Pathology

Inflammatory cells may be present along with abnormal sperm in the ejaculate of affected animals. Seminal leukocytes correlate positively with epididymitis lesions and correlate negatively with seminal quality.[496] Bacteriologic culture of the semen may aid in identifying infectious causes. Serologic tests for *B. ovis*, and *H. ovis*, are available and are helpful in determining exposure to the organisms.[411,497]

43.65.1.4 Treatment and Prognosis

Infectious causes of epididymitis are treated with systemic antibiotics selected by in vitro sensitivity. The ability of the antibiotic to gain access to the epididymis must also be considered. Treatment should continue for 1 to 2 weeks after inflammatory cells disappear from the semen. In unilateral cases, removal of the testis, epididymis, and spermatic cord on the affected side may salvage some valuable animals for breeding. If unilateral castration is elected, sequential postcastration examinations are indicated to ensure infection has not spread to remaining reproductive organs.[361]

Treatment of ram epididymitis is usually not recommended but might be attempted in valuable animals with minimal clinical signs. Oxytetracycline 10 mg/kg and dihydrostreptomycin 25 mg/kg IM twice daily for 7 days has been reported to resolve shedding of *B. ovis*.,[498]

In cases of moderate or severe bilateral epididymitis, the prognosis for recovery is poor. Obstructions and granulomas usually develop, resulting in sterility.[438] Testicular atrophy is a common sequela to epididymitis.

43.66 SEMINAL VESICULITIS (VESICULAR ADENITIS)

43.66.1 Definition and Etiology

Inflammation of the vesicular glands is uncommon in stallions but more likely in bulls.[373,374,499–501] Bacterial infections including *B. abortus*, and *P. aeruginosa*, are incriminated in stallions.[359,390,502–504] Various organisms have been isolated from cases of seminal vesiculitis in bulls including *A. pyogenes, B. abortus, M. tuberculosis*, mycoplasmas, ureaplasmas, *C. psittaci*, and *H. somnus*.,[358,373,374,499,505]

Vesiculitis may affect bulls of all ages but is most common in young growing bulls fed high-energy rations and housed together.[499] The prevalence may reach 20% to 30% in small groups of yearling bulls in close confinement.[501] The role of viral pathogens in outbreaks of the disease is not defined. Infections may arise by either ascending or descending routes from other areas of the urogenital tract, or hematogenously. Frequent homosexual activity among young bulls, high nutrition, and fast growth rates may be involved in spread of the infection.[358]

43.66.2 Clinical Signs and Differential Diagnoses

The seminal vesicles of affected stallions may be of normal size or enlarged and painful when palpated per rectum.[502,503] Stallions may refuse to cover or may be unable to ejaculate.[359] Semen contains numerous

neutrophils and blood, and fertility of infected semen is reduced.[390] Bacterial pathogens are readily recovered from semen of affected stallions.[361] However, special culturing techniques are necessary to pinpoint the seminal vesicles as the site of internal genital infection (see under Clinical Pathology).[404]

Bulls affected with vesiculitis may exhibit few clinical signs other than deterioration of semen quality. In severe cases pelvic inflammation and peritonitis result in pain reflected by reluctance to move, stiff gait, tense abdomen, and refusal to mate.[358] Other reproductive organs, particularly the ampullae, testes, and epididymides, may be inflamed.[499] The vesicular glands may not be significantly increased in size during the acute phase. If inflammation becomes chronic, the glands usually enlarge, eventually losing their lobularity and becoming fibrotic.[358,373] Abscesses are often associated with *A. pyogenes*, and may rupture into the rectum or urinary bladder.[358,374] Tubercular vesicular adenitis results in marked enlargement of the glands with caseous nodule formation. *B. abortus*, causes suppuration, necrosis, and calcification of the glands.[373] Purulent exudate is present in the ejaculate, sometimes as thick clots. Neutrophils may become less evident in semen as the condition becomes chronic. Poor sperm motility, increased morphologic defects, and an elevated pH are characteristics of semen from bulls with vesiculitis.[358]

Fertility of mildly affected bulls may remain satisfactory. More extensive involvement in which semen quality is markedly affected results in subfertility or infertility.[501] Semen from bulls with vesiculitis freezes poorly, and antibiotics used in extenders usually do not control the high numbers of bacteria present.[501]

43.66.3 Clinical Pathology

Bacterial pathogens can be recovered from the semen of affected stallions. However, without other evidence of infection of the accessory sex glands, recovery of pathogens from the semen should be interpreted with caution because the bacteria could originate from another location. Repeated samples for culture should be obtained from the sheath, penis, fossa glandis, preejaculatory fluid, urethra (before and after ejaculation), and seminal vesicle effluent manually expressed through a sterile urethral catheter positioned at the colliculus seminalis. Prostatic fluids can be collected through a catheter by massage per rectum. The first jet of a fractionated ejaculate includes the secretions of the ampullae.[404] Alternatively, a suitable fiberoptic endoscope can be passed in the urethra to the level of the seminal colliculus and into the seminal vesicles. Purulent material may then be aspirated for culture.[361]

Vesicular secretions from bulls can be collected by extension and disinfection of the penis followed by irrigation of the distal urethra with sterile saline. A sterile catheter is then passed 30 cm into the urethra, and the accessory sex glands are massaged to stimulate their secretion. Fluid is collected into sterile containers.[506]

1482

1483

43.66.4 Treatment and Prognosis

Accessory sex gland infections are treated with antibiotics selected by culture and in vitro sensitivity. Antibiotics are administered for 2 to 4 weeks, but treatment failures may occur.[390] Negligible amounts of certain antibiotics may diffuse across mucosal cell borders into the seminal plasma.[507] Properties of antimicrobials suitable for parenteral treatment of accessory sex gland infections include high lipid solubility, a favorable pKa, and low protein binding. The antimicrobial should have a pH that is basic relative to the accessory gland fluid into which penetration is desired.[508] Vesicular and prostatic fluid have a pH of 7.3 to 7.5,

whereas bulbourethral gland secretion has a pH of 8 to 8.2.[404,447] Antimicrobials that may prove suitable for treatment include the basic macrolides such as erythromycin, which is fat soluble and has a high pKa, and trimethoprim, which also has a high pKa and a high percentage of nonionized molecules in plasma, favoring diffusion across the lipid membrane of epithelial cells.[508] Because of its antimicrobial spectrum and tissue diffusion characteristics, enrofloxacin has been found to be very effective for systemic treatment of seminal vesiculitis in stallions. Treatment of stallions by lavage and instillation of antimicrobials directly into the seminal vesicles via a flexible videoendoscope can be accomplished by skilled operators. Removal of the affected gland has been performed in stallions and bulls.[502,509,510] A technique used with fair success in stallions with localized vesicular adenitis is repeated irrigation through a catheter guided into the vesicles by endoscopy. Antibiotics are instilled into the vesicular gland lumen after each irrigation.[361]

The prognosis for correction of seminal vesiculitis is only fair to poor. Animals with mild cases may recover spontaneously in 2 to 3 months. In chronic cases glands that do not abscess become fibrotic and destroyed even though purulent material does not persist in the ejaculate.[358] In stallions with vesicular adenitis, immediate filtration of the ejaculate in order to remove cellular debris and mixing of semen in an appropriate antibiotic-containing extender to control bacterial growth may maintain sperm motility and fertility.[406]

43.67 BLOCKAGE OF THE EFFERENT DUCTS (SPERM STASIS)

Blockage of the efferent ducts between the testes and penile urethra sometimes occurs in stallions. If the condition is bilateral, azospermia results in spite of apparent ejaculation. The ampullae are frequently tense, and enlargement may be demonstrated by ultrasonography.[511–513] Massage of the ampullae per rectum followed by prolonged sexual stimulation and semen collection may result in ejaculation of a semen sample with a high concentration of spermatozoa, often present as “strings” or “plugs.”[511] Large numbers of detached sperm heads, often in clumps, are commonly observed. Collection of semen on a regular schedule may aid in preventing recurrence once the blockage is relieved. Empirical treatment by blockade of β-receptors and stimulation of α-receptors has been successful in some stallions that fail to ejaculate.[514]

Sperm granulomas caused by accumulation of spermatozoa in blind efferent ducts are a common cause of infertility in the buck.[368] Granulomas have also been identified in the stallion,[515] and particularly in rams with sperm extravasation as a result of chronic epididymitis.[373,374]

44 Chapter 44 Critical Care and Fluid Therapy for Horses

K. Gary Magdesian

44.1 EQUINE FLUID PHYSIOLOGY

C. Langdon Fielding

Physiologic fluid compartments consist of total body water (TBW), extracellular fluid volume (ECFV), and intracellular fluid volume (ICFV). TBW is the most clearly defined compartment because it represents the total amount of water comprising an individual. Values for TBW in adult horses have been reported to range from 0.623 to 0.677 L/kg.[1–4] Values in foals are believed to be larger than in adult animals. In human neonates, TBW values up to 0.784 L/kg have been measured.[5] Acute changes in TBW in clinical patients can be detected with serial body weight measurements, but this becomes less accurate over long periods of time.

ECFV represents the component of TBW that is not contained within the cells. This includes plasma volume, interstitial volume, and transcellular compartments (gastrointestinal tract, joint fluid, cerebrospinal fluid [CSF], body cavities, and so on). The ECFV has been measured using a number of techniques in horses; reported values in adult horses range from 0.214 ± 0.01 to 0.253 ± 0.01 L/kg.[1,6] Estimations of ECFV in foals are significantly larger, including 0.400 L/kg in newborn foals and 0.290 L/kg in foals 24 weeks of age.[7] Plasma volume has been determined to be 0.050 L/kg in healthy adult horses and 0.090 in foals at 2 days of age.[7]

ICFV is the volume of fluid contained within cells. It has been estimated as the difference between TBW and ECFV. Bioimpedance technology has also been used to estimate the volume of intracellular space in horses, whereas standard indicator dilution techniques cannot be easily applied to the ICFV.[1,2] Reported values for ICFV in adult horses range between 0.356 ± 0.01 and 0.458 ± 0.06 L/kg.[1,2]

Rapid changes in fluid balance and compartment volumes can occur during disease states, especially critical illness. The next section discusses the physiologic relationships between these fluid volumes.

44.1.1 Plasma and Interstitial Balance

Although both are components of the ECFV, the plasma volume is separated from the interstitial space by blood vessel walls, with constant flow of fluid and proteins into the interstitial space. The plasma and interstitial volume therefore are in constant flux, and a single equation (the Starling hypothesis) describes the flow between these two spaces:

$$\text{Net capillary filtration} = K_f([P_{cap} - P_{if}] - \sigma[\pi_P - \pi_{if}])$$

where K_f is the capillary filtration coefficient, being dependent on capillary surface area and hydraulic conductivity. The other five terms in the equation represent the primary determinants of fluid balance between plasma and the interstitium:

1. π_{cap} is the colloid osmotic pressure (COP) within the capillary (capillary oncotic pressure).

COP is determined by the concentration of plasma proteins, primarily albumin, and their ability to attract ions. Normal COP in adult horses is approximately 20 mm Hg (19 to 26 mm Hg) and in neonatal foals is 18.8 ± 1.9 (15 to 22.6) mm Hg.[8,9] Hypoproteinemia with resultant decreased oncotic pressure can occur during a variety of diseases in horses but is most often a result of loss or decreased production. Losses most commonly occur through the diseased gastrointestinal tract in large animal species (protein-losing enteropathies); losses also may occur secondary to glomerular diseases or large accumulations of protein-rich effusions within body cavities or the interstitial space. Decreased production of protein (specifically albumin) occurs in response to systemic inflammation because albumin is a negative acute-phase protein.[10] Hypoproteinemia also occurs uncommonly because of liver disease.[11] Improvement of plasma COP is one of two primary means of manipulating Starling forces for fluid balance during treatment of clinical cases.

2 π_{if} is the COP within the interstitium.

Interstitial COP is more difficult to measure than plasma COP, but estimates of this number include 12 to 15 mm Hg in other species under experimental conditions.[12] Changes in total plasma protein concentration are likely to also affect the interstitial protein concentration and therefore alter both oncotic pressure components in Starling's equation. This may explain why some horses with significant hypoproteinemia do not show clinical signs of interstitial fluid accumulation (i.e., edema). That is to say, the gradient between capillary and interstitial oncotic pressure is only minimally affected when both have decreased proportionally, especially with time. It has been speculated that acute changes in plasma total protein concentration, however, may lead to edema formation more often than chronic hypoproteinemia; this is because of a relatively larger decrease in plasma protein concentration as compared with that in the interstitium with acute disease. Conversely, administration of hyperoncotic intravenous fluids (fluids with a COP >20 cm H_2O) can potentially shift the balance of oncotic pressure back to the vascular space by raising plasma COP. However, the colloid molecules from these fluids must remain within the vascular space to have this effect, which may be negated by significant alterations in capillary permeability.

3 P_{cap} is the hydrostatic pressure within the capillary

1487

Vascular hydrostatic pressure represents the pressure of plasma within the vessels pushing out toward the 1488 interstitium. A number of factors influence this pressure, including blood volume, vascular tone, and central venous pressure (CVP). This outward pressure on the vessel walls serves as the driving pressure for the continuous flux of fluid and protein out of the vessels into the interstitium. Pathologic increases in hydrostatic pressure can be caused by right-sided heart failure or other obstructive processes, such as venous thromboses, which can lead to edema formation. Pulmonary capillary hydrostatic pressure increases with left-sided heart failure and significant pulmonary vasoconstriction.

Administration of intravenous fluids can also increase capillary hydrostatic pressure; this is the second means by which therapeutic intervention can affect fluid balance between plasma and interstitial spaces in clinical patients (the first was altering plasma oncotic pressure). Fluid losses resulting from diuretic administration and acute blood loss are examples of decreased capillary hydrostatic pressure.

4 P_{if} is the hydrostatic pressure within the interstitium.

The hydrostatic pressure of the interstitium varies in different tissues but often has been overlooked as a significant contributor to fluid balance between the vascular and interstitial spaces. Newer understanding of interstitial fluid balance has recently been reviewed.[12] This information suggests that degeneration of the interstitial collagen network may cause a decrease in interstitial hydrostatic pressure, resulting in a shift of fluid into the interstitium. Inflammatory cytokines have been implicated as a cause for these changes in interstitial hydrostatic pressure. Severe burn injury can also result in marked negative pressures within the interstitium, causing a draw of fluid into the interstitial space and subsequent edema formation. In the future there may be therapeutic options to manipulate interstitial hydrostatic pressure and alter fluid balance, but currently there are no practical measures to do so.

5 σ is the capillary reflection coefficient for proteins.

Changes in capillary permeability can dramatically increase the flux of fluid and protein from the intravascular space into the interstitium. If this increase in flow cannot be balanced by a corresponding increase in lymphatic return, edema results. Increased vascular permeability has been regarded as a major mechanism of edema formation; however, it may be only one component of the significant fluid shift that results from a systemic inflammatory response syndrome (SIRS). Adult horses and neonatal foals may have significant differences in interstitial composition and vascular permeability. It has also been proposed that foals have an increased capillary filtration coefficient as compared with adults.[13] These hypotheses may explain the propensity of neonatal foals to form edema relatively easily in response to overzealous fluid administration. Because of this increased risk, careful monitoring and serial assessment of the balance between plasma volume and the interstitium is warranted when treating neonatal foals with fluid therapy.

44.1.2 Extracellular to Intracellular Fluid Volume Relationship

There are three main determinants of net movement of fluid between the ECFV and ICFV:

1 Tonicity of the ECFV

The tonicity (or effective osmolality) of the ECFV is estimated by the following equation[14]:

$$\text{Effective extracellular fluid osmolality} = (2 \times \text{Na}) + \frac{\text{Glucose}}{18}$$

Under normal circumstances, sodium and chloride are the primary determinants of ECFV tonicity; the equation doubles the sodium concentration rather than including the concentration of specific anions, some of which may not be easily measured. It should be noted that BUN is not included in the tonicity formula, because BUN is an ineffective osmole.

Other effective osmoles can be added to the ECFV, thereby increasing tonicity and inducing a shift of water from the ICFV to the ECFV. The tonicity of the ECFV is primarily regulated by vasopressin (ADH). Administration of fluids with a tonicity greater than or less than ECFV tonicity is a means to manipulate the balance of fluid between the ECFV and ICFV. This explains why hypertonic saline causes a shift of water from the ICFV to the ECFV. Recent mathematic models have been used to predict the influence of tonicity on the absolute volumes of these fluid compartments.[15] Similarly, fluid loss that has a tonicity different from the ECFV will also alter the ratio of fluid between the ECFV and the ICFV.

2 Tonicity of the ICFV

The tonicity of the ICFV is primarily determined by the intracellular concentration of potassium and its related anions. The tonicity of the ICFV and ECFV are the same at any given time point, a homeostatic mechanism meant as a safeguard to prevent acute changes in cell volume. Any imbalance in tonicity between the two fluid spaces will result in a rapid shift of fluid in order to maintain osmolar equality. The tonicity of the ICFV can be altered over time by the cells in response to changes in ECFV tonicity; an example of such a response is the production of idiogenic osmoles during hypernatremia.[16] Significant changes to ICFV tonicity during disease (resulting from damaged cell membranes) can result in accumulation of intracellular potassium, calcium, or cellular debris.

3 Cellular membrane permeability

Cell membranes are selectively permeable to water and ions. Changes in this permeability usually do not cause large alterations in global fluid balance during healthy states. However, cell membrane damage during disease states can result in significant fluid shifts. In fact, a shift of fluid from the ECFV to the ICFV is an indicator of cellular membrane damage.

44.1.3 Effects of Fluid Physiology on Clinical Fluid Therapy

Specific disease states dictate individualized fluid plans. However, with intravenous therapy the administered fluid enters the vascular space. From there, the characteristics of the administered fluid will determine its movement from the vascular space into the interstitium and from the ECFV to the ICFV. Hyperoncotic or hypertonic fluids result in the greatest relative expansion of plasma volume, with a corresponding reduction in ICFV. Hypotonic fluids result in the smallest increase in ECFV but add volume to the ICFV owing to a decrease in the tonicity of the ECFV. Estimates of the volumes of the different fluid spaces (whether based on clinical or laboratory values) before and during fluid therapy will allow for evaluation of the physiologic response in the clinical setting. The standard and universal administration of isotonic and hypooncotic fluids (such as lactated Ringer's solution [LRS] or physiologic saline) to all patients regardless of disease condition ignores the available research and clinical insight to suggest otherwise.

44.2 GENERAL PRINCIPLES FOR FLUID THERAPY IN CRITICAL CARE

K. Gary Magdesian

Current guidelines for fluid therapy in human critical care emphasize the “fluid challenge” method, believed to be more effective and safer than traditional estimates of percent dehydration.[17] The author's (KGM) protocol of fluid administration in horses follows this same algorithm. Considerations for the fluid challenge technique incorporate four primary decision phases: (1) type of fluid, (2) rate and volume, (3) goals or endpoints of fluid therapy, and (4) safety limits to fluid therapy.

1 Types of fluids include crystalloids (isotonic, hypotonic, and hypertonic) and natural and synthetic colloids. There is much controversy and no consensus as to whether crystalloids or colloids are more effective or advantageous in human critical care.[17] Currently the advantages of both fluids are capitalized on by using them together in the treatment of hypovolemia. The reader is referred to the section on fluid therapy for horses with gastrointestinal disease for further information regarding specific fluid types. Table 44-1 lists the composition of several commercially available crystalloids that are used in equine practice.

2 The rate of fluid therapy for replacement is based on the "fluid challenge" principles, whereby a 30-minute bolus of 10 to 20 mL of isotonic crystalloid per kilogram is administered with subsequent reassessment of perfusion parameters.[17] Alternatively, or in addition, hypertonic saline (7% to 7.5%) can be administered at a rate of 4 to 5 mL/kg. Colloids, because of their limited distribution in the central compartment, are bolused at slower rates than isotonic crystalloids, such as 3 to 5 mL/kg for hetastarch. Up to 10 mL of hetastarch per kilogram may be administered, being limited by development of dose-dependent coagulopathies. If after reassessment of the perfusion parameters it is deemed necessary to provide additional resuscitative fluids, then another similar bolus is given. This is repeated until signs of hypoperfusion resolve (endpoints are achieved) or safety limits are reached, at which point inotrope and/or vasopressor therapy is indicated.

Table 44-1 Composition of Commercial Replacement and Maintenance Fluids

Crystalloid	Sodium (mEq/L)	Potassium	Chloride	Calcium	Magnesium	Osmolarity (mOsm/L)	Organic Salt
REPLACEMENT							
Lactated Ringer's solution	130	4	109	3	0	272–273	28 lactate
Saline (0.9%)	154	0	154	0	0	308	0
Ringer's solution	147–148	4	156	4.5	0	310	0
Plasma-Lyte 148	140	5	98	0	3	294	27 acetate 23 gluconate
Normosol-R	140	5	98	0	3	294	27 acetate 23 gluconate
MAINTENANCE							
Plasma-Lyte 56	40	13	40	0	3	111	16
Normosol-M	40	13	40	0	3	110	16
0.45% NaCl + 2.5% dextrose	77	0	77	0	0	280	0
5% dextrose	0	0	0	0	0	252–253	0

3 The goals or endpoints of fluid therapy include both replacement and maintenance of fluid balance. *Replacement* refers to the replenishment of fluid deficits, primarily referring to those in the extracellular fluid compartment. *Maintenance fluid therapy* refers to the provision of maintenance fluid requirements to account for metabolism, insensible losses, growth, and ongoing losses. In general terms, *replacement* refers to replenishment of circulating volume and secondarily of interstitial fluid deficits; *maintenance* refers to

provision of fluids after hypovolemia and dehydration have been corrected. Maintenance fluid therapy maintains both circulating volume and hydration status, including that of the intracellular compartment.

The goals of replacement fluid therapy include rapid correction of hypovolemia by reversal of the signs of shock, including seven perfusion parameters: tachycardia (except in some neonatal foals), pale mucous membranes, prolonged capillary refill time, cold extremities, poor pulse quality, depressed mentation, and, in horses, reduced jugular fill. Urine production is another positive sign indicating correction of fluid deficits. Dehydration is corrected more slowly and is marked by reduced skin turgor (increased skin tent), dry mucous membranes, and dry corneal surface (reduced tear production).

Additional goals of volume replacement include correction of hypotension, tachycardia, oliguria, and blood lactate.[17] A decrease in urine specific gravity (in the absence of renal failure), an increase in arterial blood pressure and CVP, and improvement in venous oxygen saturation are specific endpoints. The goals of maintenance fluid therapy are different; they are to maintain a normal degree of hydration by providing for ongoing losses, including insensible losses (respiratory, cutaneous evaporative losses) and any abnormal ongoing losses such as diarrhea. Maintenance fluid rates for horses vary with ambient temperature, use, diet, and metabolic status. In general, a reasonable starting point for maintenance fluid requirements includes 2 to 3 mL/kg/hr for adult horses and 4 to 6 mL/kg/hr for neonatal foals.[18,19]

4 The safety limits to fluid therapy are indicators of intravascular volume overload, including supranormal CVP, a decrease in arterial oxygen saturation (or Pa_{O_2}), and clinical indicators of volume overload and overhydration. Once maximal CVP is achieved (10 to 12 cm H_2O in neonatal foals and 15 cm H_2O in adult horses), replacement fluid therapy must stop; if continued, edema will form as systemic and capillary hydrostatic pressures increase in response to test boluses. A decrease in oxygen saturation in arterial blood in a horse receiving fluid boluses may be consistent with development of pulmonary edema; this may precede development of tachypnea or frank edema. Although no published reports address fluid overload in clinical equine patients, one experimental study evaluating hyperhydration before moderate-intensity exercise in horses suggested the development of arterial hypoxemia during exercise.[20] These animals were administered oral fluids equivalent to 6% of body weight (approximately 26 L of isotonic fluid by nasogastric tube). Hyperhydration resulted in arterial hypoxemia, suspected to be cause by pulmonary edema associated with hyperhydration, during moderate-intensity exercise.[20] Clinical indicators serving as limits to fluid therapy include visible subcutaneous edema and tachypnea; with optimal monitoring, fluid therapy will not be allowed to continue to this point. Another endpoint or limitation to fluid therapy is a lack of further improvement in perfusion parameters despite repeated fluid boluses. If safety limits are reached before the goals of fluid therapy are achieved, the next step is to turn to inotrope and vasopressor therapy.

The reader is referred to the section entitled Fluid Therapy for Horses with Gastrointestinal Diseases for side effects of fluid therapy and principles of oral fluid therapy.

44.3 CRITICAL CARE AND FLUID THERAPY MONITORING TECHNIQUES

K. Gary Magdesian

Monitoring tools provide for advanced critical care in the large animal intensive care unit. Several of these tools are pertinent to fluid therapy and provide guidance, endpoints, and safety limits. Many of these allow for direct

monitoring of fluid during administration of therapy, whereas others provide indirect information through hemodynamic data. Both of these are important to overall case management of the critically ill equine patient.

44.3.1 Central Venous Pressure

CVP is the pressure within the vena cava; the term most commonly refers to that within the cranial vena cava. It is determined by blood volume as well as venous tone and cardiac contractility. With serial measurements CVP provides a limit to the administered volume of fluid. Normal CVP is approximately 2 to 12 cm H_2O in foals and 5 to 15 cm H_2O in adults.[21–24] Subnormal to negative CVP values signify hypovolemia; however, normal values do not necessarily imply euvolemia. This is because CVP is affected by compensatory responses such as venoconstriction.

CVP is easily measured in neonatal foals through the use of 20-cm central venous catheters, such as long-term single- to triple-lumen polyurethane catheters. Measurements can be obtained in adult horses with the use of 55-cm commercial CVP catheters. CVP can also be measured by passing a smaller gauge polyurethane catheter or polyethylene tubing through a 14-gauge, 5¼-inch standard intravenous catheter. CVP can be measured with a disposable water manometer (for spot readings) or using a pressure transducer for continuous waveforms. Interpretation of CVP waveforms requires knowledge of component waves and descents, including the a, c, and v waves and x and y descents. The a wave represents atrial contraction. The mean of the a wave is the appropriate point at which to measure CVP (at expiration). The c wave is associated with tricuspid valve closure and a bulging of the valve into the right atrium, and the v wave is caused by atrial filling from venous return. The x descent occurs after the a wave and represents the fall in pressure associated with atrial relaxation. The y descent occurs after the v wave, representing a drop in CVP caused by ventricular relaxation and reopening of the atrioventricular valves.

High CVP readings also occur with pericardial tamponade, pleural effusion, or pneumothorax, as well as false increases from catheter occlusion and air within the lines. For accurate and consistent serial results a zero reference point should be selected and used for each measurement. The top of the sternal manubrium is a good reference point for the level of the pressure transducer or water manometer. The pressure transducer or water manometer can be taped to a fluid pole, providing a fixed zero point for repeated measurements in standing horses.

It should be noted that adequacy of intravascular volume cannot be guided by any one CVP level. Precision and reliability are limited by variable zero reference points, the effects of afterload and ventricular compliance, and alterations in intrathoracic pressure.[17] There is no linear relationship between intravascular volume and filling pressures, and CVP should be regarded as only an indirect estimate of volume. Serial measurements and trends over time are more useful than single numbers. The way CVP can be used on a clinical level for monitoring fluid therapy is as follows: if the patient responds to fluid boluses without increases or with only minor increases (2 to 3 cm H_2O) in CVP, then it is appropriate to continue infusions until signs of hypoperfusion are reversed.[17] Additional guidelines used in human patients are as follows: if the CVP increases to 3 to 7 cm H_2O (2 to 5 mm Hg), the infusion should be paused and perfusion reevaluated after a 10-minute wait. If the change in CVP was an increase ≥7 cm H_2O (>5 mm Hg) after the fluid bolus, the infusion is stopped.[17]

44.3.2 Arterial Blood Pressure

Arterial blood pressure measurements provide some insight into perfusion status, particularly when used in conjunction with clinical signs and labwork, such as blood lactate. It can be measured either directly through the use of arterial catheters or indirectly with a blood pressure cuff on the tail head. Arterial lines can be placed in the great metatarsal artery of recumbent foals and the transverse facial artery in standing adult animals for direct measurements. Indirect measurements are best performed with oscillometric blood pressure monitors that provide systolic, diastolic, and mean arterial pressure (MAP). Cuffs are provided by the manufacturer and vary in width and length with size of the patient.

Arterial blood pressure in healthy neonatal foals is highly variable and depends on breed, gestational age, and size of foal. In general, normal mean arterial blood pressure (direct) is 84.4 ± 3.7 mm Hg at 1 day of age and up to 101.3 ± 4.4 mm Hg at 14 days of age.[22] Indirect blood pressure readings in thoroughbred foals has been reported as 144 ± 15, 74 ± 9, and 95 ± 13 mm Hg for systolic, diastolic, and mean pressures, respectively.[25] Direct blood pressure has been reported for adult horses: 126 to 168 (systolic)/85 to 116 (diastolic) with a range for the mean arterial pressure of 110 to 133 mm Hg.[26–29] Indirect blood pressure in adult horses is 111.8 ± 13.3 mm Hg for systolic pressure and 67.7 ± 13.8 mm Hg for diastolic pressure.[30]

1490

1491

Blood pressure values should not be regarded as the sole criteria for intervention. Rather, they should be used in conjunction with perfusion parameters, blood lactate concentration, and urine output in deciding whether there is need for further fluid administration or inotrope and vasopressor support.

44.3.3 Blood or Plasma Lactate

Blood or plasma lactate concentrations are very useful in monitoring fluid support as well as perfusion and metabolic status. Increased blood lactate may be a result of hypoperfusion and reduced oxygen delivery (hypovolemia, hypotension, anemia, hypoxemia, heart failure). Other considerations for hyperlactatemia should include SIRS, sepsis, catecholamine surges, liver or renal failure, thiamine deficiency, alkalosis, hyperglycemia, exercise, seizure activity, and the action of drugs such as salicylates and theophylline.[31–34] SIRS may increase circulating lactate concentrations independent of perfusion status; inflammatory mediators and cytokines activate pyruvate dehydrogenase kinase, an inactivator of pyruvate dehydrogenase, resulting in reduced activity of the citric acid cycle. Normal lactate concentrations in horses are <2 mmol/L, with most horses having levels <1 mmol/L.[35–37] Neonatal foals have decremental values after birth, with reported concentrations of 4.9 ± 1.02, 2.25 ± 0.6, and 0.89 mmol/L at birth, 12 hours of age, and 24 hours of age, respectively.[37–39] In a study I performed, foals had values of 2.3 ± 0.9, 1.2 ± 0.3, 1.1 ± 0.3 at 0 to 2, 24, and 48 hours of age, respectively, compared with 0.6 ± 0.2 mmol/L in adult horses.[40]

44.3.4 Cardiac Output

Advanced monitoring in equine critical care includes cardiac output measurement. A number of methods of cardiac output monitoring have bee described in horses, including the Fick principle, indicator dilution methods (such as lithium dilution), Doppler and volumetric echocardiography, pulse contour analysis, and partial carbon dioxide rebreathing. The most practical of these include lithium dilution and echocardiographic techniques.[41–46]

Lithium dilution precludes the need for placement of cardiac catheters. A small bolus of lithium chloride is injected into a peripheral vein or the cranial vena cava (via central line). Arterial blood is sampled using an arterial catheter at a constant rate and passes through a lithium electrode to generate a lithium concentration-time curve. Cardiac output is calculated from the area under the curve for lithium over time. Advantages of lithium dilution include only moderate invasiveness, good accuracy, and requirements for only small volumes of injectate. Disadvantages include the need for continuous arterial blood and limitations on repetitive measurements owing to lithium accumulation.[44–46]

Noninvasive cardiac output measurements can be made using the Bullet method through volumetric echocardiography.[43] Giguere and colleagues reported that the Bullet method provided an accurate estimate of cardiac output in anesthetized foals.[43] Cardiac output is calculated using heart rate and stroke volume (SV) as follows:

$$SV = \left(\frac{5}{6} \times LVAd \times LVLd\right) - \left(\frac{5}{6} \times LVAs \times LVLs\right)$$

where LVAd = left ventricular area in diastole (short axis view); LVLd = left ventricular length in diastole (long axis view); LVAs = left ventricular area in systole (short axis view); and LVLs = left ventricular length in systole (long axis view).

Cardiac output in healthy adult horses (400 to 500 kg) is 32 to 40 L/min.[41] Normal cardiac index, which is cardiac output expressed per unit of body weight, is 72 to 88 mL/kg/min. In the neonatal foal cardiac output has been reported to be 7.1 ± 0.4 L/min (cardiac index = 155.3 ± 8.1 mL/kg/min) in 2-hour-old foals.[22] At 24 hours of age cardiac output was determined to be 9.0 ± 0.5 L/min (cardiac index = 197.3 ± 12.0 mL/kg/min). This increased to 15.7 ± 1.5 L/min (cardiac index = 222.1 ± 21.6 mL/kg/min) at 14 days of age.[22] A general guideline for normal cardiac index is 100 to 300 mL/kg/min.[43]

44.3.5 Blood Glucose

Blood glucose concentration has been the focus of much study in human critical care in recent years. A number of studies have demonstrated improved survival and reduced complications with tight glucose control using intensive insulin therapy in critically ill humans.[47,48] Maintenance of euglycemia (80 to 110 mg/dL) resulted in reduced mortality in surgical intensive care unit patients as compared with hyperglycemia (180 to 200 mg/dL). Hyperglycemia may be associated with detrimental effects in pediatric intensive care patients as well.[49] How these findings relate to critically ill horses is unknown, but prevention of hyperglycemia is likely warranted and its effects in the equine intensive care unit require further study.

44.3.6 Monitoring Urine Analytes

Urine indices are useful for monitoring responses to fluid therapy. Successful production of urine output is a primary goal of fluid therapy, and measurement of urine production allows determination of "fluid balance" (input – output). Another important means of assessing the response to fluid loading is measurement of urine specific gravity and/or osmolarity. In the absence of renal failure, progressively dilute urine is a positive response to fluid administration. Urinalysis should be performed, and fractional excretion of electrolytes, particularly sodium, provides information regarding tubular function and can aid in differentiation

of prerenal from renal azotemia. Normal fractional excretion is <1% in adult horses and 0.31 ± 0.18% in neonatal foals.[50–53]

44.4 FLUID THERAPY FOR SPECIFIC DISEASES AND DISORDERS

44.4.1 Fluid Therapy for Liver Dysfunction and Failure (Box 44-1)

K. Gary Magdesian

Acute liver disease may result in hypovolemia owing to lack of water intake, third space losses into the gut and peritoneal cavity, and possibly pooling of blood in the portal circulation. Portal hypertension may result in gut edema with subsequent fluid loss. Considerations of fluid therapy in cases with hepatic dysfunction include reduced metabolic capacity as well as compromised synthetic ability of the liver. Because lactate clearance primarily occurs in the liver, fluids containing lactate should be avoided. Isotonic replacement fluids, such as Normosol-R (Abbott Laboratories, North Chicago, Ill.) and Plasma-Lyte 148 (Baxter Healthcare Corporation, Deerfield, Ill.), and acetated Ringer's are preferred over LRS. One millimole of acetate yields 1 mmol of bicarbonate during metabolism and is therefore alkalinizing.[54] These balanced, polyionic fluids are optimal as compared with physiologic saline because of the propensity of the latter to produce a mild, strong ion (hyperchloremic) acidosis, and many horses with liver dysfunction have a propensity toward acidemia.[55]

1491

1492

44.4.1.1 Box 44-1 Fluid Considerations for Liver Failure

1. A combination of balanced, polyionic crystalloids and colloids is optimal.
2. Acetated fluids, rather than lactate Ringer's solution, should be used.
3. Colloids, particularly plasma, can be very beneficial if hypoalbuminemia is present and to minimize third space accumulation of fluids.
4. Potassium supplementation (20 to 80 mEq/L) may aid in reducing hyperammonemia.
5. Dextrose supplementation (1 to 2 mg/kg/min) should be provided for energy support.

Provision of dextrose, even in the face of normoglycemia, should be considered unless enteral nutrition is adequate. The addition of dextrose to fluids will minimize gluconeogenesis demands on the liver, as well as catabolism of endogenous tissues with subsequent increases in nitrogen turnover (and increased ammoniagenesis). Risk of hypoglycemia from liver dysfunction is also minimized, as patients may have insufficient liver and muscle glycogen reserves and impaired hepatic gluconeogenesis to maintain normal blood glucose concentrations. A dextrose supplementation rate for adult horses is 1 to 2 mg/kg/min. This equates to 3% to 6% dextrose in fluids if 1 L of crystalloid per hour is administered to a 500-kg horse. The addition of B vitamins can be helpful for anorectic horses because they are required cofactors for oxidative metabolism. Horses that remain anorectic for longer than 24 to 72 hours should be considered candidates for parenteral nutrition.

Horses with liver dysfunction should be monitored closely for hyperammonemia as a marker of hepatic encephalopathy. Fluids can be tailored to minimize the risks of hyperammonemia. Provision of potassium provides for an electrolyte draw of hydrogen atoms from intracellular stores, thereby lowering pH and promoting ionization of ammonia to its less diffusible form, ammonium ion, which is not able to cross the

blood-brain barrier.[56] Hypokalemia also promotes metabolic alkalosis and may compound hepatoencephalopathy owing to increased urinary losses of hydrogen ion (H^+) and increased tubular absorption of ammonia. For similar reasons, sodium bicarbonate should be used judiciously and with caution in horses with a propensity toward hepatic encephalopathy. Increases in the pH of plasma will result in conversion of ammonium ion to ammonia; this facilitates the brain uptake of ammonia with subsequent intracerebral trapping of ammonium.

The rate of fluid administration for horses with liver dysfunction will vary with the volume and hydration status of the individual. In general, rates should exceed maintenance requirements to account for hypoperfusion and produce diuresis of ammonium and other toxins such as conjugated (direct) bilirubin that would otherwise have been metabolized or eliminated by the liver. Volume of fluid administration should be monitored closely in horses with ascites or portal hypertension resulting from severe liver disease because of the propensity of these patients for third space fluid accumulation. Other considerations for horses with liver disease include hypoalbuminemia, hyponatremia, hypokalemia, coagulopathies, and hyperlactatemia. Monitoring CVP will aid in preventing rises in hydrostatic pressure that would contribute to transudates or ascites.

Fluid support should be modified in horses with preexisting ascites or edema to reduce the administered sodium load. Commercially available solutions with restricted sodium concentrations (maintenance crystalloids), such as Plasma-Lyte 56 or Normosol-M, can be used in foals. Because of their availability in only small volumes (1-L bags), combinations of isotonic crystalloids and sterile water or 5% dextrose in water can be used as maintenance fluids in larger patients. If sterile water is selected, it should be allowed to mix with the isotonic fluid before entering the patient; administered alone, water could cause osmotic hemolysis. Another option in such horses is to restrict the volume of crystalloid administered through concurrent administration with colloids. Colloids expand the intravascular volume, limit the requirement for crystalloids, and may reduce the propensity of edema formation by raising oncotic pressure.

Colloids are indicated in horses with significant hypoalbuminemia (<1.5 g/dL). Hetastarch can be used at a dose of 10 mL/kg/day unless coagulopathies are present. Liver failure may result in decreased production of clotting factors or antithrombin and can initiate disseminated intravascular coagulation (DIC). Because hetastarch can induce decreased activity of von Willebrand's factor and factor VIII, as well as interfere with platelet function, it is contraindicated in horses with bleeding tendencies (after consumption of factors).[57] Plasma is an alternative colloid that has additional benefits for horses with hepatic failure. Coagulopathies associated with liver disease can be addressed through provision of exogenous antithrombin and clotting factors in plasma products. Plasma should probably not be administered to horses with serum hepatitis (Theiler's disease), as this disease is poorly understood and associated with prior administration of equine-origin biologics. Replacement of albumin is beneficial not only for oncotic pressure support but also for drug and toxin binding and as an endogenous buffer. If hypoalbuminemia is a result of hepatic dysfunction, and not urinary or gastrointestinal losses, colloids will have a longer retention time in the circulation.

44.4.2

Fluid Therapy for Diarrhea and Colitis (Box 44-2)

K. Gary Magdesian

Horses with acute colitis are often presented in a state of severe SIRS with endotoxemia, hypovolemia, and malperfusion of tissues. Fluid therapy is the cornerstone of hemodynamic and therapeutic support for these horses. Not only is circulating volume an indication for fluids, but acid-base and electrolyte derangements also warrant their use in these cases. Specifically, horses with colitis often exhibit hypovolemia, both organic and

inorganic acidoses, and hyponatremia. Organic acidosis primarily is a result of hyperlactatemia, whereas inorganic acidosis is often a result of relative hyperchloremia (or hyponatremia).

44.4.2.1

Box 44-2 Fluid Considerations for Horses with Diarrhea or Colitis

1 A combination of crystalloids and colloids has many benefits in horses with colitis.

2 Colloids are indicated when concurrent hypoproteinemia and hypovolemia are present.

3 Potassium, calcium, and magnesium should be supplemented as necessary.

4 Hypertonic saline has several potential benefits for horses with acute colitis, including volume expansion, immunomodulation, antiinflammatory effects, antiedema effects, and positive inotropic effects.

Because of the poor sensitivity of physical examination in detecting hypovolemia, estimates of percent dehydration and water deficit are not very accurate.[17] A more objective means of providing fluids is through the "fluid challenge method" described in the previous sections.[17] In this protocol a bolus dose of 10 to 20 mL of isotonic crystalloid per kilogram is administered, with subsequent reassessment of perfusion parameters. Perfusion parameters consist of mentation, peripheral pulse quality, heart rate, mucous membrane color, capillary refill time, and extremity temperature. Lactate, arterial blood pressure, and central venous oxygen saturation are perfusion monitoring tools that should be evaluated serially in patients undergoing fluid administration and can provide endpoints to fluid therapy. Urine output is another clinical indicator of improvement in perfusion in response to fluid loading. Fluid challenge should continue as repeat boluses until perfusion parameters normalize or plateau in terms of improvement. No further improvement of perfusion parameters in response to boluses of fluids suggests that inotrope or vasopressor support may be required and that further fluid therapy will not be of aid. A safety limit to fluid loading includes measurement of a high CVP value.

Crystalloid fluid choices for horses with colitis include replacement fluids, such as Normosol-R, LRS, and Plasma-Lyte 148. Normosol-R and Plasma-Lyte 148 are slightly advantageous over LRS from the stand point of providing a wider strong ion difference (sodium-chloride difference). In contrast, LRS has a chloride concentration greater than that of equine plasma (109 vs. approximately 100 mEq/L) and can compound an inorganic acidosis. Physiologic saline (0.9%) is even greater in its chloride concentration and produces a mild strong ion acidosis on administration of large volumes.[55]

Colloids are an important adjunct to crystalloid therapy, particularly for horses with hypoproteinemia such as those with acute colitis. In human critical care medicine there is no consensus as to whether crystalloids or colloids provide more successful fluid resuscitation.[17] A combination of both is likely optimal.[17] Colloids are particularly important for horses with hypoproteinemia, such as those with colitis. Concurrent hypovolemia and hypoproteinemia warrant administration of colloids in the resuscitative period, because the use of crystalloids alone could result in dilutional hypoproteinemia.[57]

Hypertonic saline (7% to 7.5%) is a rapid plasma volume expander that can be used in the early volume replacement period. Hypertonic saline increases plasma volume by three to four times the volume administered. In comparison, crystalloids increase plasma volume by only 0.25 to 0.33 mL for each milliliter administered. Hypertonic saline has additional advantages beyond volume expansion, particularly for the horse with endotoxemia. These include immunomodulatory, antiinflammatory, antiedema (particularly of the endothelium

and erythrocytes), and inotropic effects.[58–60] Microvasculature effects enhance microcirculatory perfusion, which is often disturbed during sepsis and endotoxemia. Reduction of endothelial and erythrocyte edema, two processes that contribute to multiple organ dysfunction during sepsis, results in reduced vascular resistance and blood viscosity.[59,60] The hypertonicity created by hypertonic saline evokes vasodilation, which also contributes to microperfusion when coupled with an increase in cardiac output caused by contractility-enhancing effects of hypertonic saline. The antiinflammatory and immunomodulatory effects include antiapoptosis, free-radical scavenging properties, inhibition of leukoactivation, and prevention of immunosuppression after sepsis.[58–60] In an experimental model of hemorrhagic shock in horses, hypertonic saline resulted in improved cardiac output, stroke volume, cardiac contractility and blood pressure as compared with isotonic saline.[61] Hypertonic saline has demonstrated attenuation of cardiovascular derangements in equine endotoxemia models as compared with isotonic saline.[62]

The dose for hypertonic saline is 4 mL/kg, and it should be followed with isotonic crystalloids or water to replace the "borrowed" water from the intracellular space. Hypertonic saline is generally safe but should be avoided in horses with uncontrolled hemorrhage when hypotensive resuscitation is indicated. In addition, horses with marked sodium derangements should not be administered hypertonic saline.

44.4.3 Fluid Therapy for Sepsis (Peritonitis, Pleuritis, Pneumonia, Internal Abscess) (Box 44-3)

K. Gary Magdesian

The optimal fluid for resuscitation of patients with sepsis is unknown.[63–65] Despite this controversy, a rational approach to fluid therapy in patients with sepsis is to optimize hemodynamics (increase blood pressure and urine output) while attempting to limit edema formation.[17,63,66] There is no evidence to support the use of either colloids or crystalloids over the other. Metaanalysis of clinical studies comparing crystalloids and colloids in human patient populations showed no outcome difference.[64–68] Regardless of the lack of consensus recommendations for fluid choices, fluid therapy is a keystone in the management of severe sepsis and septic shock. This is because septic shock is associated with both absolute and relative hypovolemia. Relative hypovolemia is the result of vasodilation and peripheral blood pooling in the face of cytokinemia. Volume repletion allows for increases in cardiac output and subsequently in systemic oxygen delivery.[67]

Fluid therapy in horses with sepsis is similar to that recommended for horses with acute enterocolitis; both conditions are examples of a state of SIRS. In fact, enterocolitis can be thought of as a form of sepsis. Sepsis incites a host of hemodynamic derangements that challenge fluid therapy. It causes myriad microperfusion abnormalities; these include hypovolemia, myocardial depression, vascular permeability derangements, vasodilation, DIC, and cellular changes resulting in abnormal membrane potential and membrane pump or channel function.[69] These pathophysiologic processes must be considered when a fluid plan for horses with sepsis is designed.

Sepsis is defined as concurrent SIRS and documented or suspected infection.[70] Many equine cases fall into this category, including horses with peritonitis, pneumonia, pleuritis, enterocolitis, meningitis, and metritis. Sepsis and SIRS are states of cytokine milieu, in which cytokines and inflammatory mediators predominate. Aside from antimicrobials, the fundamental therapy is hemodynamic support, consisting of fluid and vasopressor therapy.

44.4.3.1

Box 44-3 Fluid Considerations for Horses with Sepsis

1 A combination of crystalloids and colloids may have advantages in patients with sepsis.

2 The presence of concurrent hypoproteinemia and hypovolemia may be an indication for initial resuscitation with colloids.

3 Fluid challenge, consisting of 10- to 20-mL/kg boluses, is a safe and effective means of determining volume to be administered.

4 Monitoring of fluid therapy increases safety, especially in those prone to edema. Monitoring should consist of measurement of central venous pressure, arterial blood pressure, and urine output.

5 Metabolic acidosis is very common among patients with sepsis.

Initial fluid resuscitation is centered on isotonic (or near isotonic) replacement type fluids, colloids and hypertonic saline. Horses with sepsis often are presented with negative fluid balance resulting from both hypovolemia and dehydration. Fluid choices are the same as for horses with enterocolitis, and a combination of crystalloids and colloids may have advantages in sepsis.[17] Such a combination would address both blood volume and interstitial deficits, with colloids expanding the vascular space and crystalloids addressing both fluid spaces. Hypertonic saline may have some additional advantages for sepsis, including immunomodulatory, antiinflammatory, antiedema, vascular, and inotropic effects.[58–60] A dose of 2 to 4 mL of hypertonic saline per kilogram may be added to the combination of crystalloids and colloids.

Colloids are intriguing fluids for horses with sepsis. Colloids may attenuate capillary leak associated with sepsis and SIRS.[71] The exact physiology behind this colloid effect is not exactly worked out; however, theories include reduction in endotoxin-induced leukocyte-endothelial cell interactions.[72] Interactions with endothelial glycocalyx are also hypothesized in the ability of both synthetic colloids and albumin to reduce capillary leakiness.[73] Hetastarch exhibits antiinflammatory properties by reducing neutrophil adhesion and accumulation in tissues.[74] In addition, hetastarch has been suggested to be beneficial for tempering DIC in that it exerts dose-dependent effects on coagulation.[57] Hetastarch lowers concentrations of von Willebrand's factor and factor VIII:C and reduces platelet aggregability, which may aid during hypercoagulable states such as DIC.[57,75–79] Both of these properties warrant further investigation in horses with sepsis because vascular derangements and coagulopathies are quite common. It should be kept in mind, however, that bleeding may be potentiated by the administration of hetastarch to the hemorrhaging patient.[80] In a trial comparing concentrated albumin with crystalloids in human patients, there was a trend toward improved survival with albumin in patients with sepsis.[81] Concentrated equine albumin is not currently available; however, one study showed that a human albumin product could be used safely in horses.[82]

Care should be taken to avoid overexpansion of the extracellular fluid compartment with excessive fluid administration. Horses with sepsis have a predilection for edema because of the presence of concurrent hypoalbuminemia and increased vascular permeability. Therefore careful monitoring of fluid balance is warranted. *Fluid balance* refers to input and output of fluids, and it can be monitored with urinary collection systems. CVP is also useful in monitoring for safety limits in this group of patients; maximal normal CVP (10 cm H_2O in foals; 15 cm H_2O in adults) should not be exceeded. Serial ultrasonography and arterial blood gas

analysis can be used to detect pulmonary edema from relative or absolute fluid overload, before the development of gross signs (froth, crackles, tachypnea) of edema.

Because of thrombotic risks associated with sepsis-induced coagulopathies, these patients should be instrumented with minimally thrombogenic catheters, such as long-term polyurethane catheters. Attention to asepsis and cleanliness are paramount.

In human critical care "early goal-directed therapy" has been advocated by some clinical trials.[83] These studies have used goal-oriented therapeutic adjustments of preload, afterload, and contractility to achieve a balance between oxygen delivery and demand. Endpoints have included normalization of central venous oxygen saturation, blood lactate, CVP, and MAP. The therapy consisted of crystalloids and colloids for correction of CVP, vasopressors and vasodilators for MAP, and dobutamine and red cell transfusions for central venous oxygen saturation. Patients receiving this early goal-directed therapy received a greater volume of fluids early (first 6 hours of treatment) and less later, as compared with patients in the conventional group. The treatment group had a lower mortality rate and less severe organ dysfunction, highlighting the importance of early identification of patients with insidious or occult malperfusion, consisting of patients with global hypoxia yet stable vital signs.[83] There has been considerable debate over what the optimal fluid choices are for human patients with sepsis: crystalloids or colloids. The ideal fluid for volume replacement remains equivocal because concrete evidence implicating one over the other is lacking.[64,84] A current philosophy is to recognize the advantages of both fluids, with concurrent or sequential administration of both. Because crystalloids distribute approximately 75% of administered volume to the interstitium, they allow for greater interstitial expansion compared with colloids. This property is advantageous when dehydration is also present, but a disadvantage when edema is a risk. In fact, crystalloid administration further dilutes total protein and albumin concentrations, thereby lowering COP and predisposing to edema. Colloids, on the other hand, are restricted to the intravascular space and are particularly indicated in hypovolemic shock; they replace intravascular losses more rapidly than do crystalloids.[85] Colloids are associated with a plasma volume expansion between 100% and 200% of the infused volume.[86–88] In humans and anesthetized horses with colic, cardiac output is better maintained with lower volumes of fluid administration when colloids are used rather than crystalloids.[89]

Marked alterations of the reflection coefficient, as are associated with severe capillary leak and acute respiratory distress syndrome (ARDS), warrant careful consideration and monitoring of patient status when colloids are administered; because of a theoretic potential for extravascular leakage of colloids with marked endothelial alterations, patients with ARDS should be monitored closely for clinical deterioration. Despite these theoretic concerns, a new form of hydroxyethyl starch (130/0.4) has demonstrated protective effects in a model of acute lung injury (ALI).[90] The numbers after the colloid in the preceding sentence refer to the average molecular weight and degree of substitution of starch molecules with a hydroxyethyl group, respectively. This hydroxyethyl starch resulted in the best oxygenation and a reduced inflammatory response as compared with a modified gelatin colloid or Ringer's acetate crystalloid in a rabbit model of ALI.[90] Standard hetastarch has an average molecular weight of 450 kDa and a degree of substitution of 0.7; the newer hydroxyethyl starch (Voluven; 130/0.4) has been modified to have more complete renal elimination and less tissue storage than the standard product, with fewer side effects such as coagulopathies. The use of different colloids in patients with ARDS needs further study. Except for situations that may call into question the use of colloids, the concurrent use of crystalloids and colloids obviates the need for large volumes of crystalloids; this approach minimizes the risk of interstitial edema and may restore blood volume more rapidly than crystalloids alone. A "blending" of crystalloids and colloids should therefore be considered for patients with sepsis whenever colloids are not contraindicated.

Tight glucose control has been one of the very few therapeutic modalities to affect outcome in patients with sepsis. Through the use of intensive insulin infusions, glucose is regulated in the range of 80 to 110 mg/dL as compared with traditional approaches that allow for slight hyperglycemia. This direction has led to a reduction in mortality, organ failure, and septic complications in human patients.[91] Whether this approach will have similar results in horses remains to be seen. The author (KGM) uses regular insulin as a continuous rate infusion (CRI) at a rate of 0.01 to 0.1 IU/kg/hr.

44.4.4

Fluid Therapy for Renal Failure (Box 44-4)

C. Langdon Fielding

K. Gary Magdesian

Fluid therapy is the major component of therapy of renal failure in horses, regardless of cause. Hemodialysis has been reported in horses; however, it is not widely available, further highlighting the importance of fluid diuresis. Peritoneal dialysis is an option to complement fluid therapy, particularly if unresponsive anuria is present.[92,93] Development of a fluid plan for horses with renal failure begins with classification of the disease into polyuric, anuric, or oliguric renal failure. Polyuria and anuria are self-explanatory; oliguric renal failure in this section refers to a normally hydrated animal with concurrent azotemia and urine production <0.5 mL/kg/hr.

For both oliguric or anuric and polyuric renal failure, there are two primary considerations when beginning fluid therapy: fluid type and rate. The total amount of fluid administered is usually determined by the response to treatment and does not necessarily need to be identified at initiation of therapy.

44.4.4.1

POLYURIC RENAL FAILURE

The goal of fluid therapy in these patients is to induce diuresis, with removal of uremic toxins and maintenance of fluid, acid-base, and electrolyte balance.[94,95] The degree of renal failure that is reversible is often unknown at the onset; this is evaluated over time, particularly with response to fluid therapy. It should be noted that azotemia may not improve for up to 72 hours after initiation of fluid therapy when acute renal failure is severe. A lack of initial improvement in plasma creatinine or BUN during the first day or two of therapy should not necessarily prompt a poor prognosis or discontinuation of therapy.

44.4.4.1.1

Box 44-4 Fluid Considerations for Horses with Acute Renal Failure

1 Horses with acute renal failure can be either polyuric or oliguric or anuric.

2 Polyuric horses should be treated with isotonic crystalloids with the goal of diuresis. A rate of administration equal to 1.5 to 2 times a maintenance rate (3.75 to 5 mL/kg/hr) is a reasonable starting point, but input should match output. Balanced, polyionic commercial electrolyte solutions, such as Normosol-R or lactated Ringer's solution, can be used in most cases.

3 Physiologic (0.9%) saline is mildly acidifying because of hyperchloremia. Its effects on potassium balance in plasma are controversial. Hyperkalemia, commonly found in renal failure patients, can be treated with sodium bicarbonate, dextrose, calcium, and insulin when it does not respond to fluid diuresis.

4 Anuric or oliguric horses should be treated promptly. Adequacy of circulating volume and blood pressure must be ensured initially. If fluid loading with isotonic replacement crystalloids does not correct the lack of urine production, then furosemide, mannitol, and dopamine can be tried.

5 Failure to produce urine after these measures warrants hemodialysis or peritoneal dialysis.

The rate of fluid administration should facilitate diuresis.[95] A rate of two to three times maintenance fluid rate (4 to 6 mL/kg/hr, where maintenance rate is 2 to 3 mL/kg/hr) is a reasonable starting point; however, there is a paucity of literature to recommend evidence-based rates of fluid administration for treatment of acute renal failure or other disorders. Similar fluid rates have been suggested in small animal patients with renal failure.[95] It is unknown whether increases in the fluid rate beyond this point are beneficial. Certainly, if urine output is greater than this rate, it should be matched with fluid input. Measurement of CVP has become more practical in equine patients and can be used to ensure that fluid administration is not excessive.[96,97] Reference ranges of <15 cm H_2O have been reported for adult horses; values exceeding 20 cm H_2O indicate a need to decrease the rate of fluid administration to avoid development of edema.[97]

A balanced isotonic crystalloid is suitable for diuresis while preventing significant electrolyte alterations.[95] Horses should be allowed free access to water whenever possible while intravenous fluids are administered. This allows for some degree of self-regulation of water balance and can provide free water for renal excretion of the large sodium load provided by isotonic crystalloids.

Hyperkalemia is a relatively common feature of acute renal failure.[98,99] This is often corrected when renal perfusion is optimized and diuresis is instituted. When hyperkalemia is present, anuria should be ruled out. Cardiac dysrhythmias can develop during hyperkalemia; potassium free fluids (0.9% saline or isotonic sodium bicarbonate) should be administered to patients with dangerous hyperkalemia (>6 mmol/L), along with calcium, dextrose, and possibly insulin.

LRS has the benefit of containing a minor amount of free water (osmolarity 273 mOsm/L) and slightly less sodium than other fluids (130 mEq/L). A potential disadvantage, however, is that it contains more chloride (109 mEq/L) than equine plasma. Horses with renal insufficiency may be unable to excrete excess chloride provided by LRS diuresis. Mild hyperchloremia may result, causing a minor strong ion acidosis. LRS also contains potassium (4 mEq/L), which is a consideration in the hyperkalemic patient. However, studies in human renal transplant patients failed to demonstrate development of hyperkalemia as a result of LRS administration.[100]

Isotonic saline (0.9%) solution has an even higher chloride content (154 mEq/L) than LRS. In fact, neither the sodium nor the chloride concentration in this fluid is similar to those of equine plasma. Isotonic saline solution has been shown to cause hyperchloremia and a mild acidosis during prolonged administration; for these reasons it is not the ideal fluid for long-term management of acute renal failure.[101,102] Saline does not contain potassium and therefore may be warranted in horses with hyperkalemia. However, creation of a metabolic acidosis because of hyperchloremia may also pose a risk for hyperkalemia by causing an extracellular shift of potassium; this shift occurs as a result of acute changes in blood hydrogen concentration, which occur in association with hyperchloremic metabolic acidosis.[100] The effects of saline on potassium balance in horses warrant further study. Metabolic alkalosis, caused by hypochloremia or relative hypernatremia, is an indication for saline administration.

Normosol-R (Abbott Laboratories, North Chicago, Ill.) and Plasma-Lyte 148 (Baxter Healthcare Corporation, Deerfield, Ill.) have a sodium and chloride concentration most similar to equine plasma among the commercial isotonic or nearly isotonic fluids and are excellent fluids for diuresis of acute renal failure cases. It should be noted that these contain the highest potassium concentration (5 mEq/L) of all of the commercial fluids described; however, this potassium content is unlikely to contribute to clinically significant hyperkalemia in polyuric animals because of urinary excretion of excessive potassium (possible exceptions: uroperitoneum, anuria).

Isotonic sodium bicarbonate solution can be made by mixing sterile water and sodium bicarbonate to create a solution with a sodium concentration of 150 mmol/L. Isotonic sodium bicarbonate does not contain potassium or chloride and can be modified to contain an increased amount of free water as needed by lowering the sodium concentration. It exerts an alkalinizing effect by increasing strong cation (Na^+) concentrations without a corresponding increase in strong anions (i.e., strong ion alkalosis).

Blending of fluids with different compositions is also an option in order to correct or maintain electrolyte and free water balance. Over time, horses often develop a plasma electrolyte profile similar to that of the administered fluid, especially when large volumes are administered for prolonged periods; therefore combining or changing fluids may be necessary if derangements develop. It is also clear that monitoring of electrolytes (one to four times per day) is particularly important in renal patients.

44.4.4.2 ANURIC OR OLIGURIC RENAL FAILURE

Anuria and oliguria should be considered emergency medical conditions; the longer the duration of little to no urine production, the lower the chances of correcting it. Urine output in healthy horses is approximately 1 mL/kg/hr, but this may decrease by 80% (to 0.2 mL/kg/hr) in horses deprived of water.[103,104] In humans without significant fluid deficits, a urine flow <0.5 mL/kg/hr is one criterion used to define acute renal *injury,* whereas acute renal *failure* is associated with a urine flow <0.3 mL/kg/hr.[105] Oliguric renal failure should be suspected in azotemic horses with urine production <0.5 mL/kg/hr despite the administration of intravenous fluids. Once anuria or oliguria is suspected, a methodic approach to fluid administration and monitoring should be instituted immediately because of the associated high mortality rate. A delay in instituting treatment makes reversal of anuria less likely.

44.4.4.2.1 Treatment of Anuria or Oliguria

1. Obtain baseline laboratory and hemodynamic parameters. These should include serum or plasma electrolyte levels, total plasma protein and blood lactate concentrations, packed cell volume, and clinical perfusion parameters. When possible, CVP, arterial blood pressure, and central venous oxygen tension should be measured as well.

2. If CVP is not already significantly increased and there are no clinical signs of fluid overload (increased respiratory rate, peripheral edema, and so on), a fluid challenge should be initiated using 20 mL of an isotonic crystalloid per kilogram. CVP, clinical pathology, urine output, and physical examination status should be reevaluated for improvement after completion of the bolus.

3 If urine output has not significantly increased, additional fluid challenges should be given and the patient reevaluated until urine production begins or until CVP limitations are reached. A CVP value >15 to 20 cm H_2O (>10 to 12 cm H_2O in foals) signifies an endpoint to fluid administration.

4 Arterial blood pressure should be monitored. If hypotension is present despite fluid loading, inotrope and vasopressor therapy should be considered. Dobutamine can be used as an inotrope (5 to 10 mcg/kg/min). Norepinephrine, a vasopressor, can be used if dobutamine does not correct hypotension (0.01 to 0.1 mcg/kg/min). (The reader is referred to the section on inotrope and pressor therapy under Fluid Therapy for Horses with Gastrointestinal Disease.)

5 Once urine flow has increased, fluids should be continued as described previously for polyuria; careful monitoring of CVP and fluid balance (measurement of serial body weight and urine output) should be done.

6 If urine flow does not begin over the next 30 to 60 minutes with fluid challenge, furosemide should be started with an initial bolus of 0.12 mg/kg intravenously (IV) followed by a CRI of 0.12 mg/kg/hr.[106] If CRIs are not possible, a bolus dose of 1 mg/kg IV can be administered instead.

7 If urine production does not begin within 30 to 60 minutes of instituting furosemide therapy, a dose of mannitol should be administered (0.25 to 0.5 g/kg bolus as a 20% solution). If there is still no urine produced after an additional 30 minutes, another dose of mannitol can be administered; a total dose of 1 g/kg should not be exceeded in the anuric patient to prevent hypervolemia and edema formation.

8 If urine output has not improved after furosemide and mannitol, the prognosis is grave without peritoneal dialysis or hemodialysis. Treatment with low-dose dopamine has been controversial in human medicine, and several large studies have failed to demonstrate a benefit.[107,108] In fact, furosemide, mannitol, and dopamine may increase urine flow but have not been shown to unequivocally improve outcome in humans with acute renal failure.[109] When dialysis is not an option for horses with anuric renal failure, dopamine can be tried in an attempt to produce urine flow (2 to 3 mcg/kg/min); its proposed action is through increasing renal perfusion with renal afferent arteriolar vasodilation.[110] Without urine flow, there is no opportunity to provide the patient with time to heal if the acute renal injury is reversible. If dopamine is successful at reversing anuria, this time can be provided.

Hyperkalemia and metabolic acid-base disorders are common in horses with anuric or oliguric renal failure.[98] As noted earlier, hyperkalemia can be associated with life-threatening dysrhythmias. Rapid initiation of diuresis and administration of sodium bicarbonate, dextrose, and insulin are therapeutic interventions for hyperkalemia. If dysrhythmias are present, calcium should be administered to raise membrane threshold potential thereby reducing the likelihood of abnormal rhythms.

As mentioned previously, hemodialysis has been reported infrequently in horses.[92] More recently, peritoneal dialysis has been described as a cost-effective and practical approach for horses with acute renal failure.[93] These are therapeutic options in horses that do not respond to conventional fluid therapy and medical treatments of anuria described earlier.

44.4.5 Fluid Therapy for Horses with Vasculitis

K. Gary Magdesian

Horses with vasculitis present a unique challenge to fluid therapy in that they have increased vascular permeability and are therefore at increased risk for developing edema. Examples of such patients that may require restoration of fluid volume include horses with purpura hemorrhagica, type I hypersensitivity reactions (such as anaphylaxis or anaphylactoid reactions), and *Anaplasma phagocytophila* infections. Often horses with systemic vasculitis have edema, particularly in the distal limbs and ventrum, in the face of concurrent hypovolemia.

Correction of hypovolemia in these horses is challenging, as increasing the extracellular fluid compartment with crystalloid fluids may compound edema and lose efficiency in terms of blood volume expansion. Such cases may benefit from colloid administration. Depending on the degree of vasculitis and the molecular weight of the colloid, a portion of the administered colloid may also extravasate into the interstitium or third space area, compounding edema. Therefore horses receiving colloid fluids should be monitored for progression of their overall status, including increasing edema in response to fluid administration. 1496 1497

Colloids with a molecular weight of 100 to 300 kDa and those with narrower ranges, such as pentastarch (average molecular weight of 268 kDa) and the newer (third-generation) hydroxyethyl starches (molecular weight of 130), may have reduced extravasation compared with those with smaller molecular weights and wider molecular weight ranges. Colloids with this size molecule may reduce endothelial-leukocyte responses and are thought to interact with the endothelial glycocalyx in reducing capillary leakiness.[72,73] However, these are not yet available in the United States. Commercial hetastarch is heterogeneous in terms of particle size (range, 15 to 3400 kDa), and those molecules below 100 kDa could extravasate more readily.

The total amount of colloid administered needs to be considered, as doses above 10 mL/kg/day of hetastarch lead to coagulopathies.[57] The safe total cumulative dose of hetastarch over time (over days) is unknown. Plasma can be administered instead; however, albumin is relatively small (68 kDa), and much of it can redistribute extravascularly because of the altered reflection coefficient.

44.4.6 Fluid Therapy for Horses with Hypoproteinemia

K. Gary Magdesian

Similar to horses with systemic vasculitis, those with hypoproteinemia are at increased risk for edema formation with fluid therapy, making them among the most challenging to manage. The presence of concurrent hypovolemia and hypoproteinemia is a potential indication for colloids rather than crystalloids. Administration of crystalloids alone may result in compounding of the hypoproteinemia through hemodilution.[111] With altered Starling's forces, crystalloids distribute to the extracellular fluid to a relative greater extent than they would otherwise, because of a lack of plasma oncotic force for retention. Currently available colloids include hetastarch, dextrans, plasma, and concentrated human albumin.[112] Because of the increased potential for side effects associated with dextrans, there is no clear indication to use them over hetastarch. Side effects of dextrans reported in horses include muscle fasciculations, swaying of the hindquarters, tachycardia, and collapse in 8 of 64 horses.[113]

Numerous commercial equine plasma products are also currently available. Many include antibodies to salmonella, endotoxin, and clostridial organisms; these are unlabelled claims and are largely unstudied in terms of efficacy. Other advantages of plasma, especially for the hypoproteinemic horse, include provision of albumin, antithrombin, and additional clotting factors. Because albumin has multiple functions, including as a carrier protein (drugs, toxins) and physiologic buffer, plasma cannot be entirely replaced with synthetic colloids. Concentrated albumin has been used in neonatal foals, but its use in adult horses may be limited by cost.[112] The potential side effects of human plasma products in horses are largely unknown and require further study.

In one study evaluating the response of hypoproteinemic horses with gastrointestinal disease to hetastarch, it was determined that the oncotic benefit lasted 24 hours; in contrast, hetastarch raised the oncotic pressure of healthy horses for up to 5 days.[57,111] Nevertheless, even a short-term benefit in oncotic pressure may be preferable to the dilutional effects of crystalloids.

44.4.7

Fluid Therapy for Hemorrhagic Shock (Box 44-5)

K. Gary Magdesian

With the exception of prompt hemorrhage control, the key component to early trauma care is adequate fluid resuscitation. Traditionally, replacement with isotonic crystalloids of three times the volume of shed blood has been the approach in human trauma patients. Up to eight times the blood loss volume has been administered in severe shock states.

Despite its importance, high-volume resuscitation is not innocuous; ARDS has been described in patients that received massive crystalloid resuscitation after trauma.[114] Severe trauma patients enter a phase of SIRS, with some patients developing multiple organ failure and others entering a compensatory antiinflammatory response syndrome (CARS). This latter syndrome causes immune suppression and increased susceptibility to infections. Both commercial LRS, which is a racemic mixture of L- and D-lactate, and artificial colloids, namely dextrans and some hydroxyethyl starches, have proinflammatory effects.[115] It appears that the D-lactate (nonmammalian form) is largely responsible for the inflammatory reaction to LRS, because removing it from the solution eliminates this effect.[116] These fluids, both artificial crystalloids and colloids, can also cause neutrophil activation and upregulation of adhesion molecules.[117] There is currently an L-isomer form of LRS available commercially (Baxter Healthcare Corp., Deerfield, IL). Hypertonic saline, on the other hand, has been shown to be immunomodulatory and causes suppression of neutrophil oxidative burst activity and neutrophil-endothelial adhesions.[118–121] Hypertonic saline counteracts the inflammatory effects of dextrans when used in combination.[122] Therefore hypertonic saline has potential advantages for early fluid resuscitation of patients with significant blood loss, after the source of hemorrhage has been controlled. This should be followed with isotonic crystalloids, perhaps acetate-containing fluids, such as Normosol-R, or physiologic saline rather than racemic lactate. Plasma similarly does not result in inflammatory cell activation. If hetastarch is used, hemorrhage must be controlled before its administration because of its rapid volume expansion as well as dose-dependent induction of coagulopathies.[57,75–79]

1497

1498

44.4.7.1

Box 44-5 Fluid Considerations for Horses with Acute Hemorrhage

1 For horses with controlled hemorrhage, a combination ofhypertonic saline, colloids, and acetated isotonic crystalloids or physiologic saline can be used.

2 Because of experimental evidence of proinflammatory effects of racemic lactated Ringer's solution (LRS) in severe trauma, use of this solution should be questioned in cases of severe trauma until further studies are available.

3 Hypertonic saline exhibits antiinflammatory effects and may have benefits for horses with severe trauma, especially when LRS or synthetic colloids are used for resuscitation.

4 For controlled hemorrhage, a volume three to four times the estimated blood loss should be administered in isotonic crystalloids.

5 For uncontrolled hemorrhage, hypotensive resuscitation should be employed; small volumes of fluids are administered to maintain organ perfusion and a mean arterial pressure of 60 mm Hg until the hemorrhage can be controlled.

Aggressive fluid resuscitation in the face of uncontrolled hemorrhage cannot be justified. Such fluid protocols can exacerbate bleeding as a result of increases in blood pressure, disruption of clots, and hemodilution of clotting factors. Instead, a protocol of hypotensive resuscitation should be followed when bleeding cannot be stopped directly.[123] With hypotensive resuscitation, low volumes of crystalloids or whole blood should be administered to maintain organ vitality without normalizing pressures. A goal of maintaining a MAP of 60 mm Hg will still allow end organ perfusion while allowing for hemostasis.

44.4.8

Fluid Therapy in Acute Neurologic Injury (Box 44-6)

Darien J. Feary

The approach to fluid therapy in horses and ruminants with acute brain or spinal cord injury is aimed at maintaining oxygen delivery and energy supply to meet the metabolic demands of the neuronal tissue, and fluid therapy is a fundamental part of preventing or minimizing secondary neuronal injury, ischemia, and irreversible damage.

The primary goals of fluid therapy for both brain and spinal cord injury follow similar principles and include prevention and/or prompt recognition and treatment of hypovolemia and hypotension, intracranial hypertension (or cerebral edema), and glucose and electrolyte abnormalities.

Although both brain and spinal cord injuries are potentially life-threatening in large animals, acute brain injury is likely to be the most influenced, either negatively or positively, by the particular fluid therapy plan that is instituted. This is mainly because the cranial vault is a closed space, composed of brain (approximately 80%), blood (approximately 10%) and CSF (approximately 10%). An increase in one component has to result in a compensatory decrease in another. The presence of the blood-brain barrier, intact or not, is another important factor in the selection of the most appropriate fluid for management of acute brain injury.

The most important consideration in the management of cerebral injury is the maintenance of cerebral blood flow (CBF), which is often reduced postinjury. The major determinant of CBF is cerebral perfusion pressure

(CPP), which is the difference between MAP and intracranial pressure (ICP) as defined by the following equation: CPP = MAP – ICP. In the normal brain, cerebral autoregulation maintains a relatively constant CBF despite wide variations in perfusion pressure, within the range of 50 to 150 mm Hg (in humans). In the injured brain autoregulation may be impaired, often with concurrent traumatic shock and hypotension, and CBF becomes directly dependant on CPP. Therefore it becomes critical to prevent hypotension by maintaining MAP >80 mm Hg and to avoid increases in ICP that result from cerebral edema or hemorrhage. ICP is not routinely measured in large animal patients, limiting its use in guiding fluid therapy. However, neurologic signs suggestive of elevated ICP (such as obtunded mentation, mydriasis) indicate the need for specific treatment to reduce ICP, with frequent reassessment of neurologic status being important in determining response to treatment.

44.4.8.1

Box 44-6 Fluid Guidelines for Horses with Acute Neurologic Injury

1 The clinical outcome of large animal patients with brain and spinal cord injury may be improved by the prompt recognition and treatment of systemic and central nervous system hypoperfusion.

2 Isotonic crystalloid solutions appear to be the most appropriate fluids for resuscitation in acute neurologic injury, followed by careful administration of hyperosmolar therapy with mannitol or hypertonic saline if evidence of cerebral edema is present.

3 Diligent monitoring of clinical and laboratory measures of perfusion, osmolarity, and electrolyte concentrations is important for optimizing patient care and the likelihood of recovery in these patients.

Fluid management in large animal patients with acute neurologic injury is essentially based on the principles and guidelines established in human medicine from extensive laboratory and clinical studies. The ideal fluid for these human patients remains controversial and is a topic of ongoing research. When presented with a large animal patient with central nervous system injury, the clinician should formulate a fluid therapy plan tailored to the individual animal, based on findings of thorough physical and neurologic examinations and assessment of laboratory data. I suggest the following goal-directed approach:

- Goal 1—Treat hypovolemia and hypotension with adequate fluid replacement therapy to attain a normovolemic and normotensive state.
- Goal 2—Treat signs of cerebral edema or intracranial hypertension with hyperosmolar therapy.
- Goal 3—Use fluid additives to normalize glucose and electrolyte values, and provide thiamine supplementation.

44.4.8.2

REPLACEMENT FLUID THERAPY FOR NEUROLOGIC TRAUMA CASES

Although fluid restriction historically has been advocated for patients with traumatic brain injury (TBI) under the premise that intravenous fluids increase cerebral edema formation, this practice is no longer recommended, in humans or horses, for two main reasons. First, inadequate data support the theory that fluid restriction decreases cerebral edema formation, and second, systemic hypotension has been associated with increased mortality and poor neurologic outcome in human patients with TBI.[124–126]

Therefore prompt restoration of adequate intravascular volume with the goal of achieving and maintaining euvolemia and normal blood pressure should be the primary goal of fluid management in patients with neurologic injury. This is best achieved and controlled via the intravenous route in injured horses. Overhydration should be avoided, particularly in neonates, which are more susceptible to volume overload than adult horses.

Selection of the appropriate fluid for replacement therapy requires an understanding of the role of the blood-brain barrier. Because of its unique properties, the development of cerebral edema is fundamentally different from edema formation in other organs or tissues.[127] Briefly, the normal blood-brain barrier functions as a semipermeable membrane, separating the brain from the intravascular space. In the normal animal the blood-brain barrier is impermeable to large molecules (plasma proteins) but is only minimally permeable to most ions. It is freely permeable to water, however. The tonicity of the intravascular fluid, determined by its sodium concentration, influences the movement of free water across the blood-brain barrier by creating an osmotic pressure gradient between the brain interstitium and the intravascular space. In TBI the blood-brain barrier may be damaged, often producing heterogeneous regions of varying degrees of blood-brain barrier integrity and permeability. Unfortunately, demonstrating and predicting the extent of such injury in clinical patients is very difficult; the clinician often likely has to assume the presence of normal brain and functional blood-brain barrier regions for certain principles of fluid management, such as osmotherapy, to be effective.[128]

1498
1499

Hypotonic crystalloids, such as 5% dextrose in water or 0.45% saline solutions, are contraindicated in TBI patients. They lower plasma osmolarity and result in excess free water diffusion into the brain, with subsequent cerebral edema formation. Hypotonic fluids should be avoided for rapid volume replacement in patients with brain injury.

Isotonic crystalloids, such as 0.9% saline, LRS, and Normosol-R, create a minimal to no osmotic gradient across the blood-brain barrier, are readily available and inexpensive, and are therefore the current fluids of choice for replacement and maintenance therapy in brain and spinal cord injury patients.

Hypertonic crystalloids, such as 7.5% saline, create an osmotic gradient across the blood-brain barrier in favor of free water movement out of the brain, thereby reducing ICP. Hypertonic fluids are indicated *only after adequate provision of intravascular fluid volume* in horses with signs of elevated ICP or deteriorating neurologic status and are discussed in more detail in the following section on hyperosmolar therapy.

Colloids, such as plasma, human albumin, and the synthetic agents hetastarch, pentastarch and dextran, exert variable oncotic pressures and are very effective for intravascular volume expansion and maintenance. The use of colloid solutions in neurologic injury is debatable, mainly because the major determinant of fluid flux across the blood-brain barrier is plasma osmolarity, and because colloids contribute only a small number of particles in plasma, even large changes in plasma colloid oncotic pressure only minimally influence water movement across the normal blood-brain barrier. This is in contrast to the effectiveness of even small changes in plasma osmolarity.[129] In addition, the relatively higher cost of colloid solutions and the greater risk of development of hemostatic abnormalities and allergic reactions suggest little benefit of colloid solutions over crystalloids in cases of TBI. The exception is when they are used in combination with crystalloids for fluid volume expansion, provided hydrostatic pressures are not increased excessively as a result of the colloid infusion.[127]

44.4.8.3

HYPEROSMOLAR THERAPY IN BRAIN AND SPINAL CORD INJURY

If clinical evaluation of the equine patient with TBI suggests the patient has, or is at risk for developing, intracranial hypertension, then osmotherapy may be indicated. Clinical signs such as obtunded mentation, progressive mydriasis, or any deterioration of neurologic status may indicate increased intracranial hypertension. Hyperosmolar solutions exert their effect of reducing ICP by creating an osmotic gradient across the blood-brain barrier of at least a 10 mOsm/L. Studies in humans suggest that the goal of increasing plasma osmolarity without exceeding 320 mOsm/L is probably a safe and effective approach.[130] It is advisable to measure plasma osmolarity in large animal patients, at least before administration of hyperosmolar solutions, to avoid excessive increases in plasma osmotic pressure. Osmotherapy should be instituted only after restoration of adequate intravascular volume and blood pressure if CPP is to be optimized.

The two most commonly used and available hyperosmolar solutions for use in large animals are mannitol (20%) and hypertonic (3% to 7.5%) saline. Both agents have been shown to be effective in lowering ICP in human TBI patients, and although there has been recent renewed interest in hypertonic saline, studies comparing the effectiveness of the two agents have not yet demonstrated a consistent benefit of one solution over the other.

Mannitol (20%) is a six-carbon sugar with an osmolarity of 1098 mOsm/L. The recommended dose is a 0.25- to 1-g/kg intravenous bolus administered over 20 to 30 minutes, every 6 to 8 hours. The ICP-reducing effects of hyperosmolar solutions are believed to be biphasic in nature. After bolus dose administration, there is an initial plasma-expanding effect that reduces blood viscosity and hematocrit and improves rheologic properties of red blood cells, resulting in reduced ICP and improved CBF. After this immediate hemodynamic effect is a delayed osmotic diuretic effect resulting from the decreased reabsorption of sodium and water by the renal tubules, which also contributes to ICP reduction. Onset of effect of mannitol therapy is 15 to 30 minutes after bolus administration. Mannitol should not be administered as a continuous infusion for the purpose of treating cerebral edema, as it loses its plasma-expanding effects and increases the likelihood of development of side effects.[131]

The detrimental effects of mannitol are more likely to develop and become clinically significant with excessive or prolonged (>2 to 3 days) use. Side effects include hypovolemia and hypotension caused by excessive diuresis, electrolyte disturbances (hyponatremia, hypochloremia, hypokalemia, hypocalcemia), acute renal failure, and a rebound increase in ICP associated with reversal of the osmotic gradient, a phenomenon most likely explained by accumulation of the osmotic agent in brain tissue after movement across regions of damaged blood-brain barrier.[131] There is insufficient evidence to support the dogma that mannitol is contraindicated in the presence of intracranial hemorrhage.

Hypertonic (7.5%) saline has an osmolarity of 2400 mOsm/L and, similarly to mannitol, effectively reduces ICP primarily through an immediate hemodynamic effect, followed by a delayed osmotic effect. Hypertonic saline can be administered as an intravenous bolus dose (4 mL/kg) or as a CRI. Hypertonic saline may have addition beneficial effects over mannitol in TBI because of rapid augmentation of cardiac output, contractility, and MAP with administration of smaller volumes. In addition, hypertonic saline is theoretically less likely to cross the blood-brain barrier than mannitol because the reflection coefficient of NaCl is 1 (not permeable), compared with 0.9 for mannitol (more permeable). Additional benefits of hypertonic saline on

the injured brain include Na-related stabilization of cell membrane electrochemical gradients and modulation of the inflammatory response.[132]

Laboratory studies investigating the effect of hypertonic saline in resuscitation after spinal cord injury have also shown promising results, with increased spinal cord blood flow, downregulation of the inflammatory response, and attenuation of spinal cord injury.[133] Further clinical studies are needed.

Complications of hypertonic saline are uncommon and include hypernatremia and development of central pontine myelinolysis (theoretic, as it has not been reported to occur when used in cases of TBI).[130] Hypokalemia can occur because of kaliuresis in response to reabsorption of large amounts of Na in the distal tubule, as well as hyperchloremic acidosis, emphasizing the importance of regular assessment of hemodynamic and plasma electrolyte and acid-base status. Coagulopathy and bleeding complications can occur as a result of dilutional effects but are of more concern in the actively bleeding patient. Risk of hypovolemia and acute renal failure are not reported for hypertonic saline in TBI, although renal insufficiency is a relative contraindication to all hyperosmolar therapy. Rebound elevations in ICP can occur with withdrawal of therapy; therefore slow, gradual weaning of hypertonic saline infusions is recommended.[130]

1499

1500

Osmotherapy is likely to be most effective if initiated early (after isotonic fluid replacement) and with duration determined by response to therapy, with close observation and monitoring to minimize development of side effects.

44.4.8.4 FLUID ADDITIVES IN NEUROLOGIC INJURY

44.4.8.4.1 Glucose

It has been widely recognized that hyperglycemia is a common occurrence in acute brain injury in humans.[134] Hyperglycemia is believed to worsen neuronal injury and is associated with increased mortality and neurologic outcomes after TBI.[134,135] Consequently, glucose supplementation during large-volume fluid replacement should be avoided, unless the patient is hypoglycemic.

It has not been determined whether hyperglycemia after TBI is a physiologic reflection of the response and severity of injury, or if it contributes to the progression of secondary brain injury. Nevertheless, in ischemic brain tissue aerobic metabolism is impaired and excess glucose leads to lactate accumulation and intracellular acidosis via anaerobic metabolism; this can contribute to a proinflammatory and prooxidant state, thereby potentially worsening neurologic injury and increasing cell death.[130] A beneficial effect of reducing blood glucose with insulin therapy in human patients with TBI has been suggested but has not been clinically proven at this time.[136]

It is prudent to avoid hypoglycemia as well as hyperglycemia in neurologic injury. The brain is dependant on a constant supply of glucose for aerobic energy production, and glucose use may be increased after TBI, thereby increasing energy demands. These factors should be considered in the monitoring and fluid therapy plan for any large animal with neurologic injury, particularly neonates, as they are more susceptible to hypoglycemia.

44.4.8.4.2

Thiamine

Thiamine (vitamin B_1) is a water-soluble B vitamin synthesized only by plants and microorganisms. Most animals have a nutritional requirement for this vitamin, although adult ruminants and horses normally can obtain adequate quantities produced by bacteria in the rumen or cecum.

Thiamine, in its active form (thiamine pyrophosphate), plays a very important role in glucose metabolism and energy production, where it functions as a required cofactor for certain enzymes (pyruvate dehydrogenase, α-ketoglutarate dehydrogenase, branched-chain ketoacid dehydrogenase, transketolase) involved in glycolysis, the citric acid cycle, and the pentose phosphate pathway. Thiamine is also important in nerve and muscle function, where it plays a role in neurotransmission and excitation.

Thiamine deficiency is known to be associated with neurologic disease in humans and in ruminants (polioencephalomalacia). Determination of thiamine status of an animal requires measurement of red blood cell transketolase activity; therefore measurement and documentation of thiamine deficiency in clinical cases is not routinely reported. Whether or not supplementation of thiamine in acute traumatic neurologic injury is indicated is not currently supported by published evidence. However, given the increased susceptibility of damaged neuronal tissue to inadequate energy production and supply, the practice of thiamine supplementation in neurologic injury in large animals appears justified. In addition, recent experimental investigation suggests a potential neuroprotective role of thiamine in reactive oxygen species—induced neuronal injury.[137] The author (DJF) has used a dose of 5 to 10 mg of thiamine per kilogram diluted in crystalloids.

Thiamine should be protected from light.

44.4.8.4.3

Electrolytes

Sodium disturbances can have serious consequences in brain injury and should be corrected promptly if they are acute (<24 hours' duration). Isotonic fluid administration is appropriate in the majority of cases. Glucose and mannitol cause translocation of water into the extracellular fluid, and excessive amounts can lead to a clinically significant reduction in sodium concentration, as can free water administration with hypotonic fluids. If hyponatremia (Na^+ <125 mEq/L) is believed to have been present for >24 hours, then slower correction (0.5 mEq/L/hr) is needed to avoid development of central pontine myelinolysis.

Calcium is essential in maintaining cell membrane potentials and promoting neurotransmitter release. Excessive intracellular calcium accumulation is also well recognized as one of the most important pathways of secondary neuronal damage. During conditions of cerebral or spinal cord ischemia, inadequate energy supply in the form of adenosine triphosphate (ATP) leads to widespread neuronal depolarization and alterations in ion channel permeability, ultimately resulting in excessive intracellular calcium concentrations and cell death.

Serum total and ionized calcium concentrations are measures of extracellular calcium, and so the goal of targeting intracellular calcium homeostasis is limited to maintaining normal extracellular fluid concentrations at this time. Because of the known toxic effects of excessive calcium in neuronal injury, a conservative approach to calcium supplementation may be justified in the acute fluid management of large animal patients. In order to prevent the detrimental effects of hypocalcemia, one approach may be to avoid

the addition of calcium to the intravenous fluids over the initial 24 to 48 hours unless the ionized calcium concentration is <1.0 mmol/L or clinical signs of hypocalcemia are present.

Magnesium is an important cofactor in many enzymatic reactions and for the regulation of sodium and potassium transport across cell membranes through activation of the Na-K ATPase pump. Magnesium is essential for central nervous system cellular energy metabolism, modulation of excitatory amino acid transmission, and calcium channel antagonism. After neurologic injury, disruptions in the blood-brain barrier may impair regulation of CSF magnesium concentrations, and hypomagnesemia is commonly recognized in human patients with brain injury.[138] Experimental and clinical evidence suggests that a depletion of CSF magnesium concentrations is associated with the risk of secondary neurologic injury.[130] Studies also suggest a neuroprotective effect of intravenous magnesium administration after traumatic brain injury,[139] although results of other studies are conflicting.[130] Currently the dose of intravenous magnesium needed to achieve adequate CSF concentrations for neuroprotective benefits is unknown.

In large animal patients it would seem important to monitor serum total and ionized magnesium concentrations to prevent and treat hypomagnesemia after neurologic injury. Selection of intravenous fluids containing magnesium, such as Normosol-R (Mg^{2+} = 5 mmol/L) may be beneficial.

Other electrolyte disturbances identified commonly in patients with neurologic injury include hypokalemia and hypophosphatemia. A combination of decreased dietary intake and increased renal loss as a result of diuretic therapy is a likely explanation. Because of the important role of potassium in establishing normal resting membrane potential and nerve conduction, among other functions, regular monitoring and intravenous fluid supplementation if serum potassium concentration decreases to <3.0 to 3.2 mEq/L is indicated in large animal patients with neurologic injury.

1500

1501

Serum phosphate concentrations are not as routinely monitored as other electrolytes in large animal patients, and so deficiency is rarely reported. Clinical signs of hypophosphatemia usually do not manifest until serum concentrations fall below 1 mg/dL in humans and animals. It is important to recognize phosphate deficiency in patients with recent neurologic injury because it can cause or contribute to altered mental status, muscle weakness, seizures, respiratory insufficiency, and ventricular dysrhythmias. Because clinical manifestations of hypophosphatemia have not been reported in horses, it is difficult to make recommendations for supplementation. I have used a dose of 0.01 mmol/kg/hr of sodium phosphate when marked hypophosphatemia has been present in horses.

44.4.9

Fluid Therapy for Horses with Rhabdomyolysis (Box 44-7)

K. Gary Magdesian

Horses with severe rhabdomyolysis are at risk for renal failure from myoglobinuria and hypovolemia. In addition, they may develop marked electrolyte derangements from cell lysis, including hyponatremia, hypochloremia, hyperkalemia, and hyperphosphatemia.[140,141] In one study evaluating the electrolyte changes in horses with acute rhabdomyolysis, the most consistent abnormality was hypochloremia.[140] These changes have been reported in foals with rhabdomyolysis as a consequence of selenium deficiency with or without vitamin E deficiency, possibly combined with increased oxidant stress resulting from sepsis or hypoxia and reperfusion injury after parturition.[141] Three of four foals developed cardiac arrhythmias characterized by spiked T wave and decreased P wave amplitude on electrocardiographic analysis. Destruction of the major intracellular fluid compartment through extensive myonecrosis, combined with myoglobinuric renal insufficiency, produces

major fluid shifts and electrolyte derangements. In this report foals with hyperkalemia caused y rhabdomyolysis were effectively treated with mineralocorticoids, loop diuretics, and ion exchange resins to enhance elimination of potassium. Intravenous calcium, glucose, insulin, and sodium bicarbonate were also administered to help redistribute potassium back to the intracellular fluid.[141]

Metabolic acidosis is not common in horses with acute rhabdomyolysis, and alkalosis associated with hypochloremia may be more of a concern.[140] Therefore the use of sodium bicarbonate may not be indicated in the treatment of all such patients. In fact, fluids with relatively higher chloride concentration as compared with horse plasma may be optimal when hypochloremia is present. These include LRS (chloride, 109 mEq/L) and 0.9% saline (chloride, 154 mEq/L). If LRS is used, attention should be paid to serum potassium concentrations, because LRS contains potassium chloride in the amount of 4 mEq/L (see Table 44-1). LRS might be preferable over acetate-containing fluids such as Normosol-R or Plasma-Lyte 148 because the liver is the primary organ of lactate metabolism, whereas the muscle tissue plays a larger role in metabolism of acetate. In addition, the chloride concentration of these acetated fluids is lower than that of LRS. Lactate in LRS does not preclude its use in hyperlactatemic horses with muscle disorders, because hepatic metabolism of lactate occurs rapidly once plasma volume is expanded. In addition, lactate is not necessarily markedly elevated in horses with rhabdomyolysis.[142]

44.4.9.1

Box 44-7 Fluid Considerations for Horses with Rhabdomyolysis

1 Horses with acute myopathies often exhibit hypochloremia and may have concurrent hyponatremia, hyperkalemia, and hyperphosphatemia, especially when the rhabdomyolysis is severe.

2 Because metabolic acidosis is not a common finding, the indiscriminate use of sodium bicarbonate should be avoided.

3 Lactated Ringer's solution and 0.9% sodium chloride are fluids with a physiologic basis for use with rhabdomyolysis.

4 Horses with acute myopathies should be administered fluids at a rate greater than maintenance requirements in order to provide for diuresis of myoglobin.

Hereditary causes of rhabdomyolysis in horses include polysaccharide storage myopathy, glycogen branching enzyme deficiency, and recurrent exertional rhabdomyolysis (RER).[143–145] Because an alteration in muscle cell calcium regulation is a primary feature in the pathophysiology of RER, calcium supplementation of fluids administered to affected horses should be avoided.[146] Serum potassium concentrations should be monitored frequently in horses with rhabdomyolysis, because of risks associated with hyperkalemia.

Because horses with acute rhabdomyolysis are at risk for renal failure, rates of fluid administration should exceed maintenance requirements. Affected horses are usually hypovolemic and dehydrated, and in severe cases horses are myoglobinuric. Myoglobin is nephrotoxic directly, as well as indirectly causing renal arteriolar vasoconstriction and hypoperfusion. Rates of fluid administration vary with individual fluid balance and renal function, but 1.5 to 2 times maintenance requirement is a reasonable starting point. The rate can be adjusted based on the rate of creatine kinase (CK) decline and resolution of myoglobinuria.

44.4.10

Fluid Therapy for Hyperkalemic Periodic Paralysis (Box 44-8)

K. Gary Magdesian

Hyperkalemic periodic paralysis (HYPP) is caused by a genetic defect in the sodium channel on the sarcolemma, resulting in intermittent signs of sweating, muscle fasciculations, stridor, and weakness.[147] Stressors such as anorexia, anesthesia, concurrent illness, trailering, and cold environmental temperatures can precipitate hyperkalemia and onset of clinical signs. Fluid therapy for horses with hyperkalemia should be low or free of potassium. Physiologic (0.9%) saline and isotonic sodium bicarbonate (1.3%) are options. Of note is that these two fluid types have potential effects on acid-base physiology, with saline producing a mild strong ion acidosis and sodium bicarbonate a metabolic alkalosis. Another option for horses without acid-base disturbances is to combine commercial balanced polyionic fluids, such as LRS or Normosol-R, with one of these fluids. This would dilute the potassium administered from the LRS or Normosol and would minimize the effects of saline or sodium bicarbonate on acid-base balance.

1501

1502

44.4.10.1

Box 44-8 Fluid Guidelines for an Acute Hyperkalemic Periodic Paralysis Episode

1. 4 to 20 mL of 0.9% saline per kilogram, depending on severity and duration
2. 2.5% to 5% dextrose
3. 1 mEq of sodium bicarbonate per kilogram
4. 0.2 to 0.5 mEq of calcium per kilogram (0.2 to 0.5 mL of 23% calcium gluconate per kilogram)
5. For refractory cases—insulin can be added to dextrose supplementation (regular insulin, 0.01 to 0.1 unit/kg/hr)

Fluid therapy for horses experiencing stressors such as forced withholding of feed before surgery or off feed because of concurrent illness should be administered fluids with dextrose and/or calcium supplementation prophylactically at a maintenance rate. These additives may minimize the development of hyperkalemia and subsequent HYPP episodes. Calcium does not decrease serum potassium concentrations but rather protects the heart from its adverse effects by raising threshold potential. Horses experiencing an active episode of hyperkalemia or showing clinical signs of HYPP should be administered 0.9% saline, sodium bicarbonate (1 mEq/kg empirically), dextrose (2.5% to 5% for provision of 0.5 to 2 mg of dextrose per kilogram per minute), and calcium (0.2 to 0.5 mEq of 23% calcium gluconate per kilogram). Calcium and sodium bicarbonate should not be administered concurrently in the same fluid administration set because of a potential for precipitation. LRS also contains calcium, and therefore sodium bicarbonate should not be added directly to it. Administration of two 5-L bags of saline with 2.5% to 5% dextrose, with one bag containing calcium (250 mL of 23% calcium gluconate total) and the other containing sodium bicarbonate (1 mEq/kg) given sequentially, is a reasonable approach to treating an acute episode. Some horses may not require this volume of crystalloid and can be treated with less; if less volume is desired, 4 to 6 mL of saline per kilogram can be administered. Dextrose, calcium, and sodium bicarbonate can be added to 1-L bags; the sodium bicarbonate and calcium must be kept separate. In this case 5% dextrose, 0.2 mL of 23% calcium gluconate per kilogram, and 0.5 to 1 mEq of sodium bicarbonate can be used.[148]

Long-term management of horses with HYPP consists of a low-potassium diet, regular exercise, attempts to minimize stressors, and medications such as acetazolamide and phenytoin.[149] Horses undergoing chronic acetazolamide therapy could theoretically develop hyperchloremia and a tendency toward metabolic acidosis because of the effects of long-term inhibition of carbonic anhydrase. Administration of large volumes of 0.9% saline can compound hyperchloremia[62]; to minimize acidemia, it can be coadministered with isotonic sodium bicarbonate or other alkalinizing crystalloid when such horses require long-term fluid therapy devoid of or low in potassium. Phenytoin can mask the clinical signs of HYPP, even when hyperkalemia is present; it must be emphasized that phenytoin should not be the sole prophylactic medication in these horses, because hyperkalemia may be left unchecked.[149]

44.4.11 ## Fluid Therapy for Competitive Endurance Horses

C. Langdon Fielding

Endurance horses are disqualified from rides for a variety of metabolic or lameness problems. Veterinarians are responsible for the emergency treatment of horses with metabolic derangements, but there is a paucity of research available for guidance. Fluid therapy is an essential component of the therapeutic management of critically ill endurance horses.

44.4.11.1 ### GENERAL APPROACH TO FLUID MANAGEMENT OF ENDURANCE HORSES

Endurance horses experience significant fluid losses during competition; even horses successfully completing rides lose approximately 5% of body weight in water.[150,151] Horses presented for treatment of metabolic problems often exhibit clinical signs of hypoperfusion. In evaluating sick endurance horses the seven clinical perfusion parameters should be evaluated:

1 Mentation

2 Heart rate

3 Pulse quality

4 Mucous membrane color

5 Capillary refill time

6 Extremity temperature

7 Jugular fill

Urine production, when apparent, can be used as an additional perfusion parameter. In the absence of polyuric renal failure, urine output signifies renal perfusion, which is one means of assessing organ perfusion. Horses with altered mentation, persistent tachycardia (>60 bpm), poor peripheral pulse quality, pale mucous membranes, capillary refill time >2 seconds, cool extremities, or lack of urine production should be considered candidates for fluid therapy.

The rapid administration of large volumes of crystalloids is the basis of treatment at many ride events. Volume loading increases preload, thereby enhancing stroke volume, cardiac output, and subsequent oxygen

delivery. One suggested protocol for fluid resuscitation of hypovolemic endurance horses is the fluid challenge method described earlier; this consists of a bolus dose of 20 mL of isotonic crystalloid per kilogram (10 L for an average, 500-kg horse) followed by reassessment of the seven perfusion parameters. If the parameters have not improved in response to the initial bolus, then another 20-mL/kg bolus should be administered and followed by clinical reassessment. Approximately 1 hour is required to administer a 10-L bolus through a 14-gauge intravenous catheter and standard administration set; multiple catheters or those with large bores (10 gauge) can be used for more rapid administration. Affected horses may require up to 40 to 60 L of crystalloids to address hypovolemia.

Several types of intravenous crystalloids are available for administration to endurance horses. LRS and Normosol-R are balanced polyionic crystalloids commonly administered to treat hypovolemia in these horses. Specific electrolyte abnormalities may dictate the use of isotonic saline (when hypochloremic alkalosis is present) or fluid additives (potassium chloride or calcium gluconate when hypokalemia or hypocalcemia is identified, respectively). The electrolyte and serum biochemistry profiles of endurance horses that fail to finish a race are not necessarily markedly abnormal and allow the use of commercial fluids such as LRS.[151] Electrolyte monitoring identified hypokalemia as a common derangement in a small group of horses treated for metabolic disorders during a 100-mile endurance ride.(Fielding CL, unpublished data from the Western States 100-mile endurance ride, 2005 and 2006).

Calcium supplementation is common during fluid therapy of pulled endurance horses. However, results of studies examining the concentration of total and ionized serum calcium in horses during endurance rides have been equivocal as to calcium status.[150–152] If calcium is used, it can be added to fluids through the use of calcium gluconate (1 mL of 23% calcium gluconate per kilogram at a rate of 50 mL of crystalloid per liter). Calcium supplementation is required in horses with synchronous diaphragmatic flutter and should be administered until clinical signs resolve.[153] Excessive use of calcium in endurance horses may not be warranted, as it plays a role in cell death and apoptosis, particularly with reperfusion injury; supplementation of calcium in humans with rhabdomyolysis is controversial.[154]

Endurance horses with prolonged ileus or anorexia may benefit from dextrose supplementation of fluids. A dose of 1 mg of dextrose per kilogram per minute is well tolerated by adult horses and is equivalent to 3% dextrose in fluids administered at a rate of 1 L/hr for a 500-kg horse. Ideally, blood glucose concentrations should be monitored in horses administered dextrose to avoid hyperglycemia. 1502 1503

Medications commonly used in the treatment of endurance horses with metabolic derangements may affect fluid balance and should be considered in horses receiving fluid therapy. Sedatives and tranquilizers such as α_2-agonists (xylazine, detomidine, romifidine) and phenothiazines (acepromazine) have deleterious effects on cardiac output and/or blood pressure.[155,156] Drugs such as dimethyl sulfoxide (DMSO) and α_2-agonist sedatives also affect urine output and can therefore alter fluid balance.[157,158]

The following metabolic conditions are common metabolic disorders of endurance horses.

44.4.11.2

EXERTIONAL MYOPATHY

Intravenous fluid therapy is the most important feature of treatment for rhabdomyolysis. The reader is referred to the section on fluid therapy in rhabdomyolysis elsewhere in this chapter. Fluids should be administered in 10-L (20-mL/kg) boluses until urine output is achieved and the urine is grossly clear. Low doses of flunixin meglumine (0.5 mg/kg IV) are indicated for inflammation once hypovolemia is resolved

and diuresis is achieved. Adequate fluid resuscitation is indicated before release of affected horses because exertional rhabdomyolysis has been associated with severe renal failure in both humans and horses.[159,160] Horses with myopathies should be monitored closely and reevaluated within 48 hours for azotemia and progress of increased muscle enzymes.

44.4.11.3 FAILURE TO RECOVERY

Horses that are pulled from ride events because of persistent tachycardia warrant close monitoring. Such horses often require treatment at a later time. The seven clinical perfusion parameters should be evaluated thoroughly, and any animal with equivocal circulatory or hydration status should be reevaluated frequently to make sure that it is improving through voluntary eating and drinking, rather than deteriorating further. Those with clear hypovolemia or failure to improve with rest should be administered intravenous fluids as described earlier.

44.4.11.4 SYNCHRONOUS DIAPHRAGMATIC FLUTTER (THUMPS)

Synchronous diaphragmatic flutter is typically associated with hypocalcemia, and concurrent metabolic alkalosis, hypochloremia, and hypokalemia are often also present and have been implicated in its development.[161] Many affected horses are otherwise stable hemodynamically and meet all the criteria for adequacy of perfusion. Despite these findings, horses with thumps often require treatment with intravenous fluids supplemented with calcium for resolution of hypocalcemia and clinical signs. Calcium gluconate can be added to 5-L bags of crystalloid (0.5 mL of 23% calcium gluconate per kilogram per 5-L bag), and fluids with dilute calcium can be administered as a bolus. Adverse effects of rapid calcium administration include bradycardia and warrant slow administration. Many mildly affected horses would likely resolve synchronous diaphragmatic flutter with oral electrolytes and/or the consumption of feed (particularly alfalfa).

44.4.12 Fluid Therapy for Burn (Thermal) Injury (Box 44-9)

K. Gary Magdesian

Horses with severe burn injuries develop hypovolemic shock and require large volumes of balanced electrolyte replacement fluids.[162] Hypertonic saline and colloids may also be used but should be followed with isotonic crystalloids. In humans with burn injuries the guidelines for rate of administration of isotonic fluids is 2 to 4 mL/kg for each percentage of surface area burned (Parkland formula).[163] Recently a retrospective study found that significantly larger volumes of fluid (5.58 mL/kg per percent total body surface area affected) were administered to patients during the first 24 hours of hospitalization than was predicted by the Parkland formula.[164] If smoke inhalation has occurred, then the affected horse is at risk for pulmonary edema. In this case, fluid deficits should be corrected but not exceeded. Administration of excess crystalloids or high rates of fluids after resolution of hypovolemic shock will result in edema, which is detrimental to healing of burned tissues and potentially smoke-injured lungs. Once hydration is adequate, fluid therapy should be discontinued or administered at a rate necessary only to maintain hydration status. If maintenance rates of fluids are required, patients with severe burns may require more sodium than provided for by commercial maintenance fluids owing to the tremendous sodium losses through wounds.[165] In these cases, isotonic to slightly hypertonic (1.8%) crystalloids may be required.[166] Excess free water should be avoided in these patients, as it can promote intracellular tissue edema.[166]

44.4.12.1

Box 44-9 Fluid Guidelines for Burn Injury Patients

1 Hypertonic saline can be used in the resuscitative phase of burn patients but should be followed with isotonic crystalloids.

2 Colloids can be used in conjunction with or in place of hypertonic saline during fluid resuscitation.

3 Isotonic to slightly hypertonic (1.8%) crystalloids are often necessary because of tremendous sodium losses through burn wounds.

4 Plasma is an important component of fluid therapy in the severely burned patient because of the potential for protein loss.

5 Administration of excessive volumes of fluids should be avoided because edema is a common complication of burn injuries.

An important component of fluid therapy of the thermal injury patient is the administration of plasma. Significant amounts of plasma proteins are lost through cutaneous burns.[165] In addition, burn patients are at risk for coagulopathies, although this has been reported to be rare.[167] Plasma transfusions are an effective source of albumin, as well as antithrombin III for coagulopathies. Horses with significant burns can require large volumes of plasma in the first 2 to 3 days. CRI of plasma can be provided for as long as required when ongoing losses are present.

44.4.13

Fluid Therapy for Acute Respiratory Distress Syndrome (Box 44-10)

K. Gary Magdesian

ARDS presents a therapeutic challenge; because of altered Starling's forces (increased vascular permeability), affected horses and foals often have significant pulmonary edema, with protein-rich fluid.[168] Pulmonary capillary hydrostatic pressure becomes the main determinant of edema in these patients owing to the increased permeability of pulmonary capillaries.[169] Despite this propensity toward edema formation, horses and foals with ARDS should not be allowed to develop dehydration. Maintenance of normal blood volume and hydration status is critical to tissue oxygenation, including the diseased pulmonary tissue. The goal in therapy of ARDS patients is to reduce extravascular lung water while still maintaining hemodynamic stability and perfusion. In a human clinical trial, conservative fluid management in patients with ALI improved lung function and shortened duration of mechanical ventilation and intensive care as compared with patients managed with a liberal fluid strategy, although there was no difference in mortality.[170] The conservative management did not increase nonpulmonary-organ failures.[170] It should be noted that the patients in this study were volume replete and relatively stable hemodynamically. Conservative fluid therapy therefore applies to the postresuscitation phase of these patients, when administration in excess of physiologic needs can be detrimental.

1503

1504

44.4.13.1

Box 44-10 Fluid Guidelines for Acute Respiratory Distress Syndrome

1 The ideal initial resuscitative fluid choice for acute respiratory distress syndrome (ARDS) patients is unknown, but crystalloids should probably be used rather than colloids because of the risk for

compounding pulmonary edema as colloids leak into lungs. The exception would be the hypoproteinemic patient, in which plasma should be used to correct albumin deficits.

2 Hypovolemia and dehydration should be corrected, but excessive fluid volume should be avoided to minimize worsening of edema. A conservative long-term fluid plan is warranted.

3 Fluid balance in patients with ARDS should be assessed frequently; central venous pressure is a useful means of monitoring fluid balance to prevent large increases in capillary hydrostatic pressure.

Large swings in pulmonary vascular pressures should be avoided to minimize increases in pulmonary hydrostatic pressure. To avoid these wide fluctuations, intravenous fluids should be provided as a continuous infusion rather than as intermittent boluses.[171] The ideal type of fluid for volume replacement at the time of initial therapy of ARDS patients is unknown; however, colloids should be used judiciously owing to the theoretic risk of potentiating pulmonary edema through extravasation of colloids across the leaky pulmonary vasculature. This concern warrants further study; one study demonstrated no increase in net increase of transmicrovascular flux of radiolabelled colloids when COP was raised with albumin administration.[172] Isotonic crystalloids, administered at a modest rate and only to effect in normoproteinemic patients, and replacement of plasma proteins in hypoproteinemic patients are probably the safest fluid guidelines for these patients with the current level of understanding.

Patients with ALI or ARDS should be monitored closely for hypoproteinemia. Correction of hypoproteinemia in human patients with ALI benefits from concurrent administration of albumin.[173] Hypoproteinemic patients receiving both furosemide (as a CRI) and albumin had improved oxygenation, increased net fluid loss, and better maintenance of hemodynamic stability compared with those receiving only furosemide.[173] In addition, 50% of patients in the treatment group achieved resolution of the ALI or respiratory distress syndrome, compared with only 11% of controls. Consideration should be given to correction of hypoproteinemia in foals and horses with ARDS or ALI. An additional benefit of albumin is its antioxidant properties. Albumin also can reduce microvascular permeability and endothelial cell apoptosis.[174–176]

Monitoring of fluid therapy in these patients is especially important in order to avoid marked increases in pulmonary hydrostatic pressure. This can be accomplished through measurement of pulmonary capillary wedge pressure; however, this requires placement of an intracardiac catheter. Alternatively, CVP can be measured directly. This is easily performed through central lines, those placed in the cranial vena cava. In a study comparing the use of pulmonary artery catheters with that of central venous catheters in guiding treatment of ALI in humans, it was found that pulmonary catheter—guided therapy did not improve survival or organ function and was associated with more complications than central venous catheter—guided therapy.[177] The predominant catheter-related complication was development of arrhythmia. It was concluded that pulmonary catheters should not be routinely used for the management of ALI.[177]

44.4.14 Fluid Therapy for Horses with Metabolic Acidosis (Box 44-11)

K. Gary Magdesian

Both organic and inorganic acidoses are found in horses with critical illness. A common cause of organic acidosis in horses is lactate (lactic acidosis). Hyperlactatemia occurs with hypovolemia, sepsis, and SIRSs such as endotoxemia, marked hypoxemia, heart failure, cytopathic hypoxia, and liver failure.[31–34] Volume resuscitation can be performed with a combination of crystalloids and colloids, and possibly hypertonic saline.

Acetated crystalloids (such as Normosol-R or Plasma-Lyte 148) do not contain lactate; however, even LRS will correct hyperlactatemia when it is caused by hypoperfusion. Hepatic perfusion will clear the lactate previously accumulated. The exception is liver failure, where fluids devoid of lactate should be administered. Other less common causes of organic (high anion gap) acidosis include ethylene glycol and salicylate toxicity and uremic acidosis. The treatment of lactic acidosis is correction of the underlying pathogenesis. If the cause is hypoperfusion, reversal of that state should be the goal of therapy; this is accomplished through restoring blood volume, cardiac output, and finally systemic vascular resistance through the administration of fluids, dobutamine, and vasopressors, respectively. Sodium bicarbonate is therefore not a part of the routine treatment of lactic acidosis. Its use in lactic acidosis is in fact controversial.[178,179] In a canine model of lactic acidosis, the administration of sodium bicarbonate actually caused a decrease in pH and bicarbonate concentration and an increase in lactate.[180] Similarly, in a model of endotoxemia in ponies, administration of sodium bicarbonate actually increased blood lactate concentration.[181] Despite these controversies with sodium bicarbonate and lactic acidosis, when the pH of the patient's blood is below 7.2, administration of sodium bicarbonate is justified to prevent the detrimental effects of severe acidemia, even when the acidosis is a result of lactate. Severe acidosis can lead to life-threatening cardiovascular complications such as impaired contractility, sensitization to ventricular arrhythmias, and impaired responses to pressors.[182] Small doses of sodium bicarbonate should be administered slowly to increase the pH to 7.2, at which point increasing perfusion should be the goal.

1504

1505

44.4.14.1

Box 44-11 Fluid Guidelines for Metabolic Acidosis

1 The two primary forms of metabolic acidosis in horses are organic, most often resulting from hyperlactatemia, and inorganic, often resulting from relative or absolute hyperchloremia.

2 Treatment of hyperlactatemia consists of addressing the underlying cause. In many cases, lactic acidosis is caused by hypovolemia.

3 Commercial acetated fluids, such as Normosol-R or Plasma-Lyte 148, are good fluid choices for hypovolemia, although volume rather than type of fluid is the most important component of treatment.

4 The use of sodium bicarbonate is controversial in lactic acidosis and may be contraindicated.

5 Sodium bicarbonate is the treatment of choice for inorganic acidosis.

6 Sodium bicarbonate can be administered as a fluid in the form of an isotonic solution.

Inorganic acidoses occur because of strong ion acidosis associated with electrolyte derangements. In horses these commonly result from hyperchloremia or hyponatremia, both of which decrease the strong ion difference. Common diseases associated with these metabolic abnormalities include enteritis, colitis, renal failure, and renal tubular acidosis (RTA). In these cases the acidosis is often caused by renal or gastrointestinal dysfunction of electrolyte homeostasis, and perfusion may be normal (i.e., normal lactate). Chronic administration of carbonic anhydrase inhibitors, such as acetazolamide, is another cause of hyperchloremia. The fluid of choice for patients with hyperchloremic metabolic acidosis is one containing only strong cations without strong ions. Because sodium bicarbonate contains only strong cations (sodium), it is an ideal choice for patients with normal anion gap (hyperchloremic) acidosis. Sodium bicarbonate should be administered slowly to allow time for distribution and evaluation of its effects. As a fluid choice, rather than as a supplement, isotonic (1.3%) sodium bicarbonate can be used; this formulation contains 150 mEq each of sodium and bicarbonate ion per liter. Potential side effects of sodium bicarbonate therapy include hypernatremia, hypokalemia, ionized

hypocalcemia, vasodilation, metabolic alkalosis (if in excess), and an increased affinity of hemoglobin for oxygen (left shift of the oxygen dissociation curve).[181]

44.4.15 Fluid Therapy for Heart Failure (Box 44-12)

K. Gary Magdesian

The cardiac patient represents a unique challenge to fluid therapy. Volume expansion poses significant risk to the horse with heart failure by raising venous pressures and potentiating sodium retention. Administration of sodium-containing fluids can lead to or compound edema and body cavity effusions. Despite these risks, patients with heart failure sometimes require fluid therapy, such as when they develop anorexia, renal failure, or diarrhea. Monitoring of CVP should be performed in these patients to aid in prevention of edema. Initial fluid therapy should consist of conservative rates, with frequent reassessment of the effects of fluids on the patient. Continuous, slow administration of fluids, rather than boluses, should be employed to avoid rapid swings in CVP. Any rise in CVP should be avoided in horses with heart failure.

44.4.15.1 Box 44-12 Fluid Guidelines for Heart Failure

1 Horses with heart failure are intolerant of significant changes in central venous pressure.

2 Fluid boluses should be avoided, and fluids should be administered at a slow, continuous rate.

3 Consideration of the amount of sodium administered should be a priority.

4 Conservative fluid rates are warranted.

5 Concurrent and careful use of diuretics may be indicated.

The choice of fluid depends largely on concerns over sodium retention in the heart failure patient. Fluids with lower sodium content may be preferable, such as maintenance fluids (0.45% NaCl/2.5% dextrose, Plasma-Lyte 56, or combinations of replacement fluids mixed with sterile water).[183] As soon as the patient is able to drink water the intravenous fluids should be discontinued.

Because of sodium retention in heart failure, these horses are often treated with diuretics such as furosemide, which aid in minimizing edema formation.[183] A fine balance between fluid therapy and diuretics is required.

45 Chapter 45 Principles of Antimicrobial Therapy

Consulting Editors

Gordon W. Brumbaugh

45.1 PRINCIPLES OF ANTIMICROBIAL THERAPY

Gordon W. Brumbaugh

"Rational therapeutics" is the scientific account of the management and care of a patient for the purpose of combating a disease or a disorder based on knowledge of the disease and the action of the remedies used. It requires clinical judgment, overall medical knowledge, information about a specific patient,[1] selection of the proper drug, and the formulation of a dosage regimen appropriate to the patient after appraisal of potential benefits and risks of that therapy.[2] That process is not simplified by the vast number of antimicrobial drugs available. It is therefore essential that basic principles be applied so that antimicrobial drugs may be appropriately selected and used in patients. The purpose of this chapter is to explain general principles of rational antimicrobial therapy (Box 45-1) rather than to discuss individualized treatment of specific infectious conditions. Guidelines for prudent use of antimicrobial drugs have been published by several professional associations and organizations. Guidelines are by nature inherently dynamic and can be general or very specific, but in either case they should follow a principled approach.[3]

The ultimate expectation of an antimicrobial drug is to inflict an insult on an infectious organism that is sufficient to kill the organism or to render it susceptible to lethal effects of natural host defenses or the microenvironment around it, without adversely affecting the patient.[4,5] To accomplish this goal, antimicrobial drugs must be selectively toxic to the infectious organism.[6,7] Different structures, biochemical activity, virulence factors, mechanisms of resistance, generation times, and nutritional requirements of infectious organisms (i.e., bacteria, viruses, fungi, and parasites) form the mechanistic basis for selective toxicity of antimicrobial drugs. No individual drug is sufficient to meet all therapeutic needs. It is irrational to treat a viral infection with antibacterial drugs or a bacterial infection with antiparasitic drugs. However, principles of selection and use of antimicrobial drugs are similar regardless of the infectious agent.

45.2 PRINCIPLE 1: CONSIDER THE PATIENT

The patient occupies the paramount position with regard to treatment and recovery from infection. Although the organism is the target of the drug's action, it is the *patient* with an infection that receives the drug. Before the patient can be considered adequately recovered, infectious agents must be controlled and removed from the site of infection, debris must be removed from the site, and the damaged tissue must be repaired or replaced.[8] Inactivation of microbes is the *only* role played by antimicrobial drugs; the patient must participate in that aspect and perform the others. Most infections are prevented by efficient nonspecific host defense mechanisms.[9] When infections occur, many patients recover without treatment because of nonspecific and specific host defense mechanisms. Ideally, if the host's defenses are functional and a pathogen's virulence can be weakened by antimicrobial drugs, the host should be able to kill and remove the microbe.

Many host-related factors must be considered during the formulation of a therapeutic plan.[10,11] The animal's age, sex, breed, use, residence, contacts with other animals, travel, diet, exposure to inclement weather, vaccination status, and medical experiences may influence natural defenses in the animal and prevalence of certain infections. Prevalence of an infectious disease may vary with year, susceptible population, and geography. Medical history of the herd may also be of value because virulence of some infectious agents may change after "passage" through several animals.

Clinical signs must be interpreted carefully because identification of the agent is frequently not possible on the basis of clinical signs alone.[10] Clinical manifestations of infection result from direct effects of microbial pathogens, their toxins, or the inflammatory response elicited in the host. Similar clinical signs may be caused by different microbial agents, and one species of microbe may produce a variety of clinical signs.[12] Signs of noninfectious conditions can mimic those of infectious conditions.

Inadequacies in host defense mechanisms are as important as the organism's virulence in determining whether infection will result from contact with an infectious agent and whether recovery will result if infection develops.[9] This is exemplified by infections associated with combined immunodeficiency syndrome or failure of passive transfer. It is irrational to expect antimicrobial drugs to resolve those conditions because the primary problem is not an "antimicrobial deficiency." Reasonable attempts should be made to assess weaknesses in a host's defenses that may contribute to the disease. Natural defenses of note include skin, mucous membranes, mucociliary escalator activity, cough reflex, transit time through the gastrointestinal tract, blood supply at portals of entry of infectious agents, humoral and cellular immunity, and resident microflora.[13] It is not possible to assess many of these objectively in most clinical situations. The attending veterinarian must have astute clinical acumen to subjectively evaluate contributory factors. Attempts should be made to replenish temporarily inadequate host defenses. If the host's defensive response contributes to clinical signs (e.g., if inflammatory edema compromises breathing), the response should be modified to enhance convalescence.

Antimicrobial drugs can alter the response of the host's immune system or the stimulatory antigen.[14] The outcome of complex interactions among antimicrobial drugs, bacteria, and phagocytic cells depends on the organism, the drug, its concentration, and the duration and timing of exposure to the phagocyte and microbe.[15] Antimicrobial therapy of proven efficacy should not be withheld from a patient to potentially enhance that animal's immunity. Effects of antimicrobial drugs on chemotaxis, phagocytosis, metabolism of neutrophils, and the complement system are demonstrable in vitro but have inconclusive or insignificant clinical importance.[14] Inhibitory effects of chloramphenicol or rifampin on cellular and humoral immunity have been studied most extensively, but their immunomodulatory effects are not sufficient to warrant restricting their clinical use. Clinical consequences of effects of antimicrobial drugs on immunity are limited but should be conservatively considered. For example, florfenicol did not interfere with responses of cattle vaccinated against bovine herpesvirus type 1.[16] Tilmicosin had neutrophilic antiinflammatory activity in cattle that were experimentally infected with *Mannheimia (Pasteurella) hemolytica*.[17] Some antimicrobial drugs accumulate in phagocytes, but increased bactericidal activity is not equally correlated to the degree of that accumulation; likewise, no relationship has been demonstrated to clinical response.[18,19]

1506

1507

45.2.1

Box 45-1 Principles of Antimicrobial Therapy

1 Consider the patient.

2 Document the infection.

3 Determine microbial susceptibility in vitro.

4 Use an appropriate dosage regimen.

5 Monitor results of treatment.

6 Investigate causes of therapeutic failure.

7 Restrict concomitant use of antimicrobial drugs.

8 Appropriately attend adverse reactions to drugs.

45.2.2 Special Considerations

45.2.2.1 MATURATIONAL STATUS

An animal's responses to pharmacologic agents are significantly influenced by the age or maturity of the animal.[10,20,21] Physiologic differences that alter disposition of drugs in vivo are primarily responsible for that. Pharmacologic effects of xenobiotics (chemicals that are foreign to the biologic system) administered to brood animals before conception, during gestation, or at parturition or to neonates are not universally predictable. Drugs may distribute into gonads at sufficient concentrations to adversely affect gametogenesis. Drugs in luminal fluids of the oviducts or uterus may be teratogenic. Distribution of drugs into the placenta and fetus is affected by factors such as placental circulation, placental maturation, placental and fetal biotransformation of drugs, and fetal circulation. Among these variables, species-related differences may occur. Therefore drugs should be administered conservatively to brood animals, pregnant animals, and neonates and with adequate explanation of pertinent facts to the client. Potentiated sulfonamides administered to gestating mares for treatment of equine protozoal myelitis were shown by Fenger and colleagues to be associated with increased incidence of anemia, fever, anorexia, depression, and abortion.[22] Stallions treated with potentiated sulfonamides and another diaminopyrimidine (pyrimethamine) were shown to develop signs of neuromuscular weakness and ejaculatory dysfunction.[23] It is not clear how each of these signs could be attributed to these drugs. Indirect effects such as folate deficiency may account for some of the adverse signs that have been observed. Some adverse findings with one species should be interpreted with care when dealing with another species. Anemia is a good example. An aspirate or biopsy of bone marrow is necessary to adequately evaluate anemia in horses, whereas peripheral blood may be sufficient with other species.

Biotransformation of drugs in neonates can be altered by administration of medication to the gestating dam. Phenylbutazone administered to gestating mares during the final days of gestation resulted in substantial amounts of phenylbutazone and of oxyphenylbutazone in plasma of their foals.[24] Although phenylbutazone is not an antimicrobial drug and results of similar studies with antimicrobial drugs are not known to us, this example serves to emphasize the importance of considering peripheral effects of medication administered to gestating animals.

Fluoroquinolones are known to cause cartilaginous arthropathies in weight-bearing joints of young animals of several species. The horse may be unique in that adult horses have also developed the same syndrome,

which was inconsistently related to dose and duration of treatment with enrofloxacin.[25,26] Tissues peripheral to plasma contained higher concentrations of fluoroquinolones than did plasma; therefore accumulation from repeated dosage regimens should be considered when developing those regimens.[25,27–29] Although arthropathic syndrome has now been recognized and acknowledged as a risk associated with use of fluoroquinolones, nothing is known about the healing and recovery of joints that are injured. Therefore the overall assessment of risks of treatment with those drugs remains speculative; anecdotal reports suggest that the injured cartilage may repair and not carry prolonged clinical consequences, but that needs to be confirmed.

45.2.2.2

LACTATION

There are at least three aspects to consider regarding distribution of drugs into milk: the lactating animal, the suckling animal, and the milk-consuming public. Distribution of drugs into milk is influenced by the same factors that influence distribution of drugs into other tissues.[10,21,30] Some antimicrobial drugs are concentrated in milk, others equilibrate between milk and circulating blood, and still others reach insignificant concentrations in milk (Table 45-1).[31–39] A ratio greater than 1 indicates accumulation of the drug in milk relative to plasma. Results often vary with pH of milk. Concentrations of tetracycline may be high as a result of chelation with calcium but remain bioinactive.

Therapeutic implications of the distribution of drugs into milk are clear, but inflammation of the mammary gland may alter distribution of drugs. Mastitic milk may resemble an exudate rather than “milk,” thus providing a different microenvironment from that of milk. Nearly all drugs administered to a lactating animal will be detectable in her milk and can thereby expose the suckling animal. However, the total amount of most drugs received by the suckling animal via milk does not pose significant concerns.[20]

Antimicrobial drugs in milk may render that milk unsuitable for use as food.[30] Subtherapeutic concentrations of drugs in milk may cause no adverse effect, may cause the milk to be condemned as adulterated, may interfere with production of cheese or other dairy products, or may induce reactions in an allergic person who consumes the milk. For these reasons, compliance with and adherence to withdrawal times should be considered seriously.

45.2.2.3

WITHDRAWAL TIMES

Withdrawal times are intended to allow adequate time for elimination of the drug from the animal to reduce the risk of violative residues of drugs inadvertently entering the food supply. Withdrawal times are established for drugs that are licensed for use in animals intended for use as food, and the withdrawal time applies only when the drug is used according to the approved labeling.[13] Because of this, it is important 1507
before treatment is initiated to discuss the patient's condition with the client, to determine if the animal 1508
(regardless of species) is intended for use as food, and to ascertain if extralabel use of the drug is needed. Without such a discussion the client cannot make a wise decision regarding the risks and benefits of therapy, and precautions to prevent adulteration of food may be inadvertently omitted.

Table 45-1 Ratio of the Concentration of Drug in Ultrafiltrate of Milk to That in Plasma After Systemic Administration of the Drug[31–39]

Drug	Ratio (Range) (Milk: Plasma)	Reference
Ampicillin	0.24–0.30	28
Benzyl penicillin	0.13–0.26	28
Cephaloridine	0.24–0.28	28
Erythromycin	6.00–7.30	29
Gentamicin	0.20–0.50	30
Kanamycin	0.60–0.80	30
Lincomycin	2.50–6.25	31
Spectinomycin	0.37–1.12	32
Sulfacetamide	0.08–0.11	33

Tylosin	1.00–5.35	32

Withdrawal times are not established for drugs that are used in an extralabel manner; therefore the most conservative time should be allowed when drugs are used in a manner inconsistent with their labeling.[40,41] Aids to determine useful withdrawal times include screening tests for drugs in milk* or urine.† Results may not match those of methods used by regulatory agencies assigned the task of detection of residues, and those agencies may test different tissues.

45.2.2.4

EXTRALABEL USE OF DRUGS

Veterinarians often encounter infectious conditions for which the drug of choice is not approved by the U.S. Food and Drug Administration's Center for Veterinary Medicine (FDA-CVM).[13] In these situations the veterinarian is not exempt from professional and ethical obligations. Treatment must be based on experience, established practices, and scientifically substantiated facts. Drugs that are used in any manner other than that described on the drug's labeling (e.g., the treatment of diseases, with doses, routes of administration, duration of treatment, or species not specified on the approved labeling) are said to be used in an *extralabel* manner.

The Animal Medicinal Drug Use Clarification Act (AMDUCA)[40] of 1994 amended the Federal Food, Drug, and Cosmetic Act so that a particular use or intended use of a drug shall not be deemed unsafe if such use or intended use is (1) by or on the lawful written or oral order of a licensed veterinarian within the context of a veterinarian-client-patient relationship, and (2) in compliance with regulations promulgated by the Secretary of the U.S. Department of Health and Human Services. In short, the amended act contains statutory allowance of extralabel use of drugs, and regulatory authority is retained by the FDA-CVM. For veterinarians to discharge their professional duties within the public trust and in an ethical manner, a professional approach to extralabel use of drugs is necessary. Some guidelines include the following:

- A valid licensed veterinarian—client-patient relationship
- A medical diagnosis
- A situation in which approved use of a drug has proven ineffective in animals being treated or for which no available drug is specifically labeled (as is often encountered with some species)
- Carefully maintained identity of treated animals
- Observation of extended withdrawal times calculated by the attending veterinarian[42]
- Acceptable labeling of the prescribed drug[13,42–44]

Regulations specify contents of acceptable labeling. Consultation with a representative of the FDA-CVM is advised before treatment is initiated when particularly perplexing therapeutic problems exist and no alternatives to extralabel use of drugs are apparent.

45.2.2.5

HERD TREATMENT

Each member of a herd may have the same disorder, but one animal cannot receive treatment that is intended for another (there are no surrogate patients), and treatment of an animal that does not need it is wasted treatment. Treatment must be implemented for each affected animal in the herd. The method of treatment must be practical and efficacious, or compliance by the client will be difficult. Unfortunately, requests by some owners and veterinarians for “herd treatment” are really requests to treat each animal identically and easily rather than according to its individual needs. Each animal may indeed require the same treatment, and treating all animals in question may be acceptable, but each animal deserves a reasonable assessment of its condition before treatment is instituted. Metaphylactic or therapeutic medication of all animals has benefits and risks, but the cost must be offset by savings in areas such as labor of handling of the animals, reduced needs for therapeutic medication, or improved production.[45,46]

45.2.2.6

COST OF THERAPY

The cost of appropriate therapy is an important consideration for the client. The client (or his or her financial advisor) is the only one who can decide whether the value of treatment is “worth” the “cost.” The cost of medical care is not static, and the veterinarian should keep the client informed of the financial commitment associated with treatment. Naturally, cost-effective therapy should be sought. This is not to say that the least expensive therapy is the best therapy or that ineffective drugs should be used just because they are inexpensive. Similarly, expensive drugs are not “better” just because they cost more. Clients require adequate information to make financial and medical decisions regarding their animals.

45.3 PRINCIPLE 2: DOCUMENT THE INFECTION

Antimicrobial therapy is predicated on the premise that the disease is caused by an infectious agent and that the patient will be unable to effectively eliminate the infection without antimicrobial treatment.[1,4] The primary purpose of documentation of infection is to help the veterinarian determine the necessity of this treatment. Clinical experience and diagnostic and interpretive skills are particularly important. Use of antimicrobial drugs for relatively trivial infections exerts selective pressure for resistant organisms.[5] Contamination or colonization by microorganisms (i.e., contamination of the surface of granulation tissue) does not necessarily constitute infection and is not always a sufficient reason for antimicrobial treatment. Inoculum size, microbial virulence, concurrent infection, site of infection, and resident flora contribute to the significance of infection. Death resulting from some bacterial diseases such as botulism (except toxicoinfectious botulism), enteric colibacillosis, or enterocolitis caused by salmonellae is not directly caused by vegetative bacterial invasion, so antimicrobial drugs are a secondary component of treatment. Without evidence of involvement of a susceptible causative agent(s), use of an antimicrobial drug is irrational and exposes the patient to unnecessary risks.[1] The more information that can be discerned about the infecting agent, the more reasonable will be the treatment.[1,11]

1508

1509

Sequential steps necessary to document an infection are as follows[1,47]:

- Development of reasonable suspicion of infection based on the patient's clinical signs and the veterinarian's knowledge of the pathophysiologic and microbiologic characteristics of the condition
- Careful procurement and submission of a representative sample of material from the lesion
- Initial detection of organisms by microscopic examination of a stained smear of the sampled material
- Demonstration and identification of the infectious agent in vitro, on the basis of its morphologic, immunologic, or biochemical characteristics
- Serologic evidence of antibodies produced against a particular infectious antigen
- Interpretation of the results of all diagnostic procedures

There are nonspecific and specific methods of documenting infection.[10] Nonspecific methods include medical history, clinical signs, hematologic changes, and characteristics of lesions. The drug(s) used for initial therapy will most often be selected on the basis of the veterinarian's clinical judgment and medical knowledge, as well as on nonspecific indications of infection.[2,11,47] This is not a trial-and-error approach.[48] Potential for a particular infectious cause, most probable causative agent, status of the patient's natural defense mechanisms, and site of infection must be considered when interpreting clinical signs.[49] “Response to treatment” is an inconsistent means of revealing the cause of infection. Although nonspecific methods are the weakest form of documentation, that information, coupled with astute clinical judgment, is often successfully used in practice. For example, a young horse with fever, nasal discharge, and submandibular lymphadenitis can be assumed (with a relatively high degree of certainty) to have strangles, and penicillin could be chosen for therapy. However, the possibilities for misdiagnosis are numerous in this and many other disease conditions, and specific methods of documenting infection should be used. An aspirate obtained from involved lymph nodes of the patient in the example may reveal chains of gram-positive cocci, and *Streptococcus zooepidemicus* may be isolated. The immediate treatment may not change, but the management of the rest of the animals in the herd would differ greatly from that indicated for strangles.

Different organisms may be susceptible to and successfully treated with one antimicrobial drug, making treatment choice easy. However, a specific causative diagnosis may be of considerable relevance for the development of herd-health programs.

Antimicrobial therapy cannot be consistently successful if formulated on the basis of nonspecific diagnostic methods and historical probabilities alone.[10] Treatment formulated in that manner may cause more harm than good by interfering with the pursuit of a specific diagnosis, by allowing the development of superinfection, or by inducing reactions to the drugs.

Specific diagnostic methods should be attempted before initial treatment is instituted. Specific methods of documenting infection require proper collection and submission of appropriate samples, reliable laboratory procedures, and accurate interpretation of results. Because laboratory facilities and personnel can work only with materials submitted to them, the veterinarian must properly collect and submit appropriate samples to the laboratory and interpret results relative to the condition of the individual patient. Procurement of tissues or bodily fluids for cytologic, histologic, or microbiologic evaluation remains the cornerstone of accurate documentation of a specific infection.[10] Inadequate or improper sampling and improper submission of samples to the diagnostic laboratory are the most frequent and often unrecognized reasons for failure of documentation of causative agents of infectious diseases. The sample must be representative of the site of infection and may be bodily fluid (blood, peritoneal fluid, pleural fluid, percutaneous transtracheal aspirate, material draining from a site of infection) or tissue (biopsy, scraping, curettage, aspirate). Collection and submission procedures differ for aerobic and anaerobic bacteria, mycoplasma, protoplasts, viruses, and parasites. Special media or particular constraints of time and temperature must often be observed to transport fastidious organisms. Because each laboratory may use different techniques, it is wise to contact laboratory personnel in advance to learn preferred collection and submission equipment and procedures. The veterinarian and laboratory personnel can assist each other in reducing inappropriate collection and submission practices.

The choice of site to be sampled is critical. Isolates from draining tracts are unreliable and should be evaluated in the context of other related information.[50] Organisms isolated from wounds are of questionable significance unless they are present in pure culture or are clearly predominant. In these instances susceptibility testing is probably warranted. Any microorganism isolated from bodily fluids that are normally sterile (blood, cerebrospinal fluid (CSF), pleural fluid, or synovial fluid) in the presence of clinical evidence of infection should be evaluated for its antimicrobial susceptibility in vitro. If dissemination of infection is suspected, isolation of the agent from samples obtained from sites distant from the primary site of infection will strengthen confidence in the diagnosis.[10] Cultures of blood samples should be performed if dissemination is suspected because of systemic signs or if no primary site of infection is apparent. It is important to properly prepare the site of venipuncture so that the sample does not become contaminated. Results of cultures may be difficult to interpret if such details are ignored. The type of sample to be submitted (biopsy, feces, fluid, aspirate, blood) is selected on the basis of the disease. Recommended sites and materials to be sampled are presented in discussions of specific diseases elsewhere in this text.

If the patient has received antimicrobial drugs, the collection procedure should be delayed until the drugs are adequately eliminated from the animal's body so that residual drugs will not interfere with bacterial growth. Because approximately 99% of a drug will be eliminated from the body within seven half-lives of disappearance, an appropriate delay between treatment and sampling can be estimated if pharmacokinetics of the drug are known. However, the delay calculated by this method may not be appropriate for severely ill patients. A fairly reliable rule of thumb is to wait 18 to 36 hours after the last dose of a drug. If a repository form of the drug is used, a longer delay is indicated. If the patient's condition does not permit a delay, the probability of isolating organisms

from bodily fluids can be increased if samples are passed through a device designed to remove antimicrobial drugs from the sample.* Directions for use of such a device should be closely followed. If samples are obtained for culture at the time of a necropsy, the treatment history may be important for interpretation of results of subsequent antibiograms.

Evaluation of stained smears of samples remains the most rapid and useful method of early recognition of some infectious agents.[1,10] A direct smear should be made from a part of the sample, stained, and evaluated microscopically for bacteria and to characterize the cytologic response. Gram stain for bacteria, Wright stain for cytologic examination, acid-fast stain for mycobacteria, methylene blue and potassium hydroxide preparations for fungi, India-ink preparations for cryptococci, darkfield microscopic examination for spirochetes, fresh wet mounts for motile organisms (trichomonads), phase-contrast microscopy, immunofluorescence, and electron microscopy are methods of identification of infectious agents and inflammatory cells by direct examination. Techniques of DNA typing and polymerase chain reaction (PCR) are finding their place as modern diagnostic procedures for identifying some organisms.

Knowledge of morphologic and staining characteristics of bacteria is important to predict the identity of the microorganisms observed in the smear (Box 45-2).[1] Gram or Wright stain will demonstrate the presence of most microorganisms. If only one stain is used, Wright stain* is preferred because its cytologic staining is superior to that of Gram stain. Characteristics of the microorganisms (fungal, bacillary, or coccoid bacteria), the nature of the inflammatory cells, and suspicions of which microorganism(s) might be present at the site of infection are especially beneficial for deciding initial treatment. With this information, treatment can be rationally initiated at least 24 hours before results of cultures are known and within minutes of the time that diagnostic samples are obtained. Although the list of those organisms is shrinking, some microorganisms respond predictably to certain antimicrobial drugs. Other organisms respond unpredictably because of genetically related resistance, which may arise by mutation, induction, or acquisition of a plasmid. If gram-negative bacilli are seen in samples, at least one member of the unpredictable class of microorganisms should be suspected. If one or more unpredictable species are present, isolation and antimicrobial susceptibility procedures must be performed.

Serologic methods of diagnosing infections may be beneficial.[10] However, because most patients have recovered from infections by the time a convalescent sample is obtained, serologic diagnoses may not be available in time to influence treatment. However, serologic data may be beneficial for the development of preventive strategies. The class of immunoglobulin and the timing of its production are determined by the previous antigenic experience of the host. High concentrations of specific immunoglobulin M (IgM) are useful in diagnosing certain viral infections and toxoplasmosis. Acute and convalescent sera demonstrating a fourfold rise in the concentration of a specific IgG indicate the presence of infection. Samples of serum should be obtained at an interval of 2 to 3 weeks to permit an adequate time lapse for the formation of significant amounts of IgG. Although the presence of IgG in a single serum sample, regardless of concentration, indicates exposure to the agent, it is of little assistance in diagnosing a current infection. There is no consensus about what constitutes adequately protective concentrations

of immunoglobulins. Because serologic response is used to diagnose some conditions, is the presence of immunoglobulins an indication of infection, protection, vaccination, or passive transfer?

Documentation of infection entails more than merely listing isolated microorganisms on a laboratory report. The veterinarian must decide if the isolated organisms could be responsible for the condition in the animal, if they are commensal, resident flora, or if they are merely contaminants resulting from improper sampling technique. For example, *Escherichia coli* isolated from a sample of feces from a calf does not indicate that the calf's diarrhea was caused by that organism. However, if that isolate was shown to possess the K99 pilus antigen and the ability to produce enterotoxin and if the signalment and clinical signs are compatible with coliform enteritis, the veterinarian can establish a cause-effect relationship from the bacterial presence.

45.4 PRINCIPLE 3: DETERMINE MICROBIAL SUSCEPTIBILITY IN VITRO

Quantitative assays of a microbe's susceptibility to antimicrobial drugs in vitro are necessary for patients with severe or complicated infectious processes and for those with infections caused by organisms with unpredictable susceptibility patterns.[1,10,51,52] It is important to remember when formulating a therapeutic strategy that "the bug denotes the drug."[4] A microbe is considered sensitive to a drug if the concentration of the drug that inhibits growth of the organism in the testing system in vitro can be achieved in vivo after administration of the drug by methods customarily used in clinical situations. Two commonly used quantitative assays of susceptibility are broth dilution and disc diffusion tests.[6,10,50–54] Reliability and reproducibility of these procedures depend on the organism examined, standardization of the inoculum, medium used, conditions of incubation, and concentrations of the drug. The development and promotion of performance standards, as well as interpretive criteria, for in vitro antimicrobial susceptibility testing of bacteria isolated from animals is the mission of the Subcommittee on Veterinary Antimicrobial Susceptibility Testing of the Clinical and Laboratory Standards Institute (CLSI).* Results of these procedures can be coupled with knowledge of the clinical pharmacology of potentially useful drugs and of pathophysiologic changes in the patient to design an individualized dosage regimen for the patient.

1510
1511

Broth dilution procedures involve inoculation of a known number of organisms into tubes or wells holding a volume of broth that contains specific concentrations of antimicrobial drugs. These inoculated tubes or wells are incubated under standardized microenvironmental conditions. The lowest concentration of antimicrobial drug that inhibits visible bacterial growth is defined as the minimum inhibitory concentration (MIC) of that drug for that organism. The lowest concentration of antimicrobial drug that prevents bacterial growth, when an aliquot of the inoculated broth that contains no visible growth is subcultured onto drug-free agar or into broth, is the minimum bactericidal concentration (MBC). Therefore the MIC is a measure of the bacteriostatic concentration of the drug, and the MBC is a measure of the bactericidal concentration of the drug. Drugs that are by some conventions classified as bactericidal have an MBC within one or two twofold dilutions of the MIC. The adjectives *bacteriostatic* and *bactericidal* should be used to describe concentrations of drugs rather than to classify drugs. The disk diffusion susceptibility test involves application of antimicrobial drug-impregnated paper disks onto inoculated agar plates. The antimicrobial drug diffuses from the disk into the agar, and a progressively decreasing gradient of concentrations of the drug is developed centrifugally around the disk. If the drug is active against the organism, a growth-free zone will surround the disk. The size of the growth-free zone can be correlated with the MIC determined by dilution assays. Because multiple factors affect diffusion of drugs in the medium, the size of the growth-free zone induced by one drug cannot be equated to a zone of the same size induced by another drug.

The microdilution method provides information that may be more clinically relevant than that offered by the agar dilution method for determining therapy for bacterial infections of animals. The quantitative endpoint of susceptibility can be correlated with concentrations of the drug in bodily fluids or tissues. As a result, a more informed choice of treatment can be made than is usually possible when using agar dilution methods.

Standards for susceptibility in vitro do not necessarily apply to activity against pathogens that can be found within phagocytes in the patient. Results of intracellular antimicrobial activity were not predictable based on data from standard susceptibility procedures and have generated additional questions about the wisdom of generalizing susceptibility information in vitro or as predictable of clinical response.[18,19]

Laboratory reports of susceptibility of microorganisms to antimicrobial drugs provide only part of the information needed to formulate appropriate therapeutic actions. Interpretation and application of that information remain the responsibility of the veterinarian. It is reasonable to assume that if the same conditions are present at the site of infection as in vitro, the results obtained in vitro could also be expected in vivo. However, standardized microenvironmental conditions of a system in vitro are seldom present in the patient, and those conditions in the patient are usually unknown to the attending veterinarian. Temperature, humidity, partial pressures of oxygen and carbon dioxide, pH, osmotic pressure, presence of debris from damaged tissue, inactivating substances, and nutritional substrates at the site of infection are as important to therapeutic success as is the concentration of the drug. Limitations of susceptibility procedures and difficulties encountered with interpretation and application of results are eclipsed by the benefit provided. During recent years the clinical relevance of categorizing organisms as “susceptible,” “intermediate,” or “resistant” has been questioned. Although it is generally agreed that patients with “susceptible” organisms should respond successfully to those antimicrobials, classification of organisms as “intermediate” or “resistant” is not necessarily associated with clinical failure. Retrospective and prospective studies, as well as studies with models—computerized and laboratory animal—have been undertaken to resolve the dilemma, but accurate predictors of clinical outcome remain elusive.[55] Niederman states that the clinical relevance of resistance is overemphasized.[3] Other investigators emphasize that the outcome of microbe, antimicrobial, and host defenses is dependent on time and concentration of medication to which the microbe is exposed, regardless of medication evaluated.[18] Those times and concentrations may be clinically relevant but beyond those used by standard procedures in vitro. Several reports demonstrate that being a member of a subpopulation of patients, categorized by disease, organism, and concurrent health issues, has significant influence on final clinical outcome.[3,56,57] Metlay conveys concerns that changing treatment patterns based on perceptions of clinical relevance of resistance rather than on scientific evidence severely limits the ability to continue to monitor effectiveness of available treatments; yet clinical effectiveness continues to be the primary factor driving selection of antimicrobial medication.

Although the previously mentioned evidence germinated in human medicine to form the basis for development of treatment protocols, similar data for veterinary patients are severely lacking.

* Clinical and Laboratory Standards Institute (CLSI), Wayne, PA.

45.5 PRINCIPLE 4: USE AN APPROPRIATE DOSAGE REGIMEN

In most instances there are insignificant differences in clinical response after bactericidal or bacteriostatic therapeutic protocols.[53,58] Bacterial meningitis, endocarditis, and gram-negative bacillary infections in neutropenic human patients are conditions in which bactericidal concentrations of active drugs at the site of infection were correlated with improved response. Confirmatory data with animal patients are lacking, but extrapolation may be acceptable when similar causative organisms are present. Because of complex interactions

among microbes, subtherapeutic concentrations of drugs, postantimicrobial effects, host defenses, and microenvironment at the site of infection, dogmatic statements about the requirement for bactericidal protocols should be avoided.

The drug selected for treatment must reach the site of infection, at an adequate concentration of the active form(s), for a sufficient time that its selectively toxic effect can be inflicted on the infectious agent. Astute application of clinical judgment and knowledge of pathophysiology and clinical pharmacology are important for the development of an appropriate dosage regimen so that therapeutic success may be expected.

A dosage regimen has six components: formulation of the drug to be used, dose of drug to be administered, route of administration, site of administration, dosing interval, and duration of treatment.[10,59] When the appropriate drug has been selected, dose, route, site, and interval of administration can be formulated using pharmacokinetic values of the drug in the targeted species. The drug's bioavailability, its distribution to the site of infection, the duration of therapeutic concentrations at the site of infection, and its clearance from the body must be considered. The following are affected by drug- and host-related factors: solubility of the drug and its formulation in water and lipids, formation of a concentration gradient, blood flow at the site of absorption and at the site of infection, ionization of the drug, binding of the drug to proteins, biotransformation of the drug, chemical characteristics of the drug, presence of an inflammatory response, and microenvironment at the site of infection.

1511

1512

Postantimicrobial effects of some drugs may be significant. These effects can be considered with pharmacokinetic values and mathematically factored into the calculation of a dosage regimen.[60] Few patients have conditions that require detailed mathematic calculation of a dosage regimen. Patients that may require such attention are those with compromised function of organs involved with biotransformation or elimination (primarily liver or kidneys), those that need treatment with drugs that are potentially toxic, and those that receive two or more drugs that interact in a potentially dangerous manner or that alter biotransformation or elimination of themselves or other drugs. Diligent monitoring of the high-risk patient for evidence of insult or toxic damage to organs is recommended (e.g., routine urinalysis, blood urea nitrogen, creatinine, sorbitol dehydrogenase).

The ability of an antimicrobial drug to distribute to an infected site depends on circulating concentrations of the drug, molecular size, binding of the drug to proteins in plasma and in tissue, water and lipid solubility of the drug, ionization of the drug, inflammation, active transport mechanisms, affinity for the particular tissue, and rate of elimination.[10,18,53,61] Increased blood flow and capillary permeability associated with inflammation at the site of infection allow passage of drugs into areas that might otherwise be inaccessible. The blood-brain barrier poses such a barrier to drug passage. Distribution of penicillins and cephalosporins into CSF and other tissues is inversely proportional to the degree of plasma protein binding of the drug and directly varies with the degree of inflammation present. Aminoglycosides enter the CSF poorly, regardless of the presence of inflammation. However, no drug completely equilibrates across the blood-brain barrier; therefore high systemic concentrations of drugs are necessary to achieve adequate concentrations in the CSF, unless the intrathecal route of administration is used.

For reasons and by mechanisms that aren't totally understood, some drugs, particularly macrolides, concentrate in tissues and remain in those tissues for expended periods.[3,19,55,57] Those characteristics are at risk of being misinterpreted because specific contributions to clinical outcome are not clear. Also, the time course of those drugs in plasma, as described by classical pharmacokinetic methods and as used typically for pharmacokinetic and pharmacodynamic (PK/PD) modeling, do not adequately apply to the time course in the target tissue. Therefore for macrolides, typical PK/PD modeling does not adequately serve as a predictor of clinical outcome.

Drugs may be concentrated along routes of elimination and used advantageously to treat infections along those routes. However, when usual pathways of excretion are impaired, therapeutic success may fall, and drug-induced toxicity becomes more likely. Drugs that concentrate in urine can be used to treat urinary tract infections, even though concentrations of those drugs in blood may be ineffective against infection elsewhere (e.g., benzathine penicillin G or ampicillin trihydrate in the horse). This illustrates the necessity for relating the susceptibility of the organism to the concentration of drug at the site of infection. Penicillins, cephalosporins, trimethoprim-sulfonamide, and other drugs that attain high concentrations in urine may be effective against organisms that are otherwise considered resistant. Similarly, drugs that are eliminated by the biliary route may be used to treat biliary or hepatic infections. Drugs that undergo significant biliary elimination or reach beneficial concentrations in the liver include erythromycin, chloramphenicol, tylosin, and tetracyclines.

Duration of treatment varies with the disease and individual patient.[3] Activity of the host's defenses and ability of the organism to resist those defenses, mechanism(s) by which the organism develops resistance to the drug, location of the infection, and primary activity of the drug influence decisions about the duration of therapy. If antimicrobial drugs are truly necessary for the patient, one dose of the drug(s) is seldom sufficient unless the product is designed for prolonged exposure of the pathogen to adequate concentrations. Usually, treatment continues beyond resolution of the patient's clinical condition. Duration of treatment remains a judgment call of the attending veterinarian.

Microenvironmental conditions at the site of infection must be compatible with the selected drug. Supernate of fluid from abscesses is acidic, hyperosmotic, and hyperionic, with relatively low concentrations of sodium and chloride and high concentrations of potassium and phosphate.[62] Relative to the respective concentrations in serum, concentrations of calcium are lower, those of magnesium are higher, and those of albumin and protein are lower in abscesses. Regarding drugs with intracellular sites of action, only that part of the drug that is nonionized, unbound to proteins or other constituents, and escapes inactivation by enzymes or competitive compounds crosses the bacterial plasma membrane to reach the site of action to be therapeutically active. Penicillins and cephalosporins inhibit synthesis of the bacterial cell wall, but death of bacteria occurs when the bacteria rupture as a result of the relatively hyperosmolar interior of the bacteria. If the extracellular microenvironment is isosmolar relative to the interior of the organism, a cell-wall variant (protoplast or spheroplast) may form and continue to survive.[6,63]

Aminoglycosides are ineffective in an anaerobic microenvironment because the oxygen-dependent transport system that is necessary for intracellular uptake of the drug by susceptible bacteria is nonfunctional in an anaerobic environment.[6,53,62] Drugs that are extensively bound to proteins in plasma are also extensively bound to proteins in pus.[62] In addition to binding to proteins, aminoglycosides and polymyxins bind to constituents in sediment of pus from human patients. Binding of gentamicin is reversible and does not inactivate the drug. The antimicrobial activity of gentamicin may be inhibited as much as 16- to 32-fold by the acidic pH, high ionic content, and osmolality of pus. Activity of microbial β-lactamase at the site of polymicrobial, anaerobic infection can be sufficient to reduce the concentration of effective β-lactam antimicrobial drugs. Debris from tissue may provide adequate substrates for bacteria to circumvent effects of trimethoprim or sulfonamides.[6,64]

Size and purity of the inoculum also influence antimicrobial activity. A certain number of molecules of aminoglycosides is needed to kill a single bacterium; therefore antimicrobial activity is influenced by the amount of active drug relative to the size of the inoculum.[53] Many infections are polymicrobic, and antimicrobial activity at the site of infection is influenced by complex interactions among microbes, the host, and antimicrobial drugs that are not influential in susceptibility test systems in vitro.[62]

The effect of most antimicrobial drugs is best when the pathogen is actively growing and dividing, because at that time the organism is most susceptible.[6] When infections mature, bacterial growth rates are reduced, and bacterial population density increases.[53] Mature infections caused by gram-positive cocci respond poorly to delayed treatment. Effects of delayed treatment against *Bacteroides fragilis* have been demonstrated with metronidazole, clindamycin, cefoxitin, and moxalactam. Metronidazole was the least affected by delay. A group of β-lactam antimicrobial drugs, the penems, have good activity against slowly growing bacteria.[65] They have been used in animal patients, but their applicability in veterinary medicine will be better defined by results of well-designed studies.

1512
1513

A drug formulation administered to animals of different species or to different animals of the same species may have different pharmacokinetic characteristics. Pharmacokinetic characteristics may be altered by disease and can vary from animal to animal. Pharmacokinetic studies are usually performed with healthy animals; pharmacokinetics of drugs in diseased animals may be substantially different. Pharmacokinetic values are used to describe the time course of a drug in the body and to predict what will occur if the drug is administered to another animal. If predicted values do not accurately describe the time course in diseased animals, those predicted values are not acceptable, and data from appropriately designed studies with diseased animals should supersede previous data. A calf with hypovolemic shock associated with gram-negative bacteremia and endotoxemia may have inadequate peripheral perfusion with subsequent inadequate absorption of drugs administered intramuscularly. Because of individual variation, this principle can be remembered as "the horse directs the course"[4] or "the cow dictates how."

A good example of this is found in the combination of trimethoprim and sulfadiazine. The pharmacokinetics of both drugs are relatively similar in both horses and cows. However, in cattle the time course and circulating concentrations of each drug differ significantly.[66–68] Absorption of trimethoprim appears to be the limiting factor affecting circulating concentrations of that drug when it is administered extravascularly. However, this should not be considered as an overall impediment to the efficacy of this combination of drugs. Efficacy has been demonstrated experimentally against salmonellosis in calves[68]; its efficacy against urinary tract infections cannot be adequately judged by circulating concentrations of these drugs.

45.6 PRINCIPLE 5: MONITOR RESULTS OF THERAPY

It is surprising to note that optimal therapy (drug, dose, route, dosing interval, duration, and ancillary treatment) against pulmonary infections in people is not inflexible or established.[3,57,58] The same is probably true for infections in animals. It is extremely difficult to determine the minimally effective dosage regimen of a drug; therefore the veterinarian must monitor, by appropriate means, results of treatment.

Without monitoring the therapeutic response, the veterinarian is unable to assess success or failure of treatment. Assessment should continue throughout the treatment period.[3,10] Nonspecific and specific methods used to document infection can also be used to monitor therapeutic response. Intervals at which these procedures should be performed depend on the type, severity, and site of the infection. Clinical signs, morbidity, mortality, hematologic changes, radiologic signs, microbial reduction, and monitored concentrations of drugs are useful in assessing success of therapy; but each has inherent limitations and none is clearly superior.[3,56,57] Measurement of concentrations of some antimicrobial drugs in serum or plasma is an aid to assessing adequacy of the dosage regimen and reducing risks of toxicity.[50] Therapeutic drug monitoring is most applicable when patients are receiving aminoglycosides, have impaired function of organs of elimination or biotransformation of the drugs, or

receive more than one drug, which may result in adverse interactions.[50,69] Therapeutic success against bacterial endocarditis is more likely when the patient's serum (with drug) will inhibit bacterial growth in a 1:8 or higher dilution and will kill the organisms in a 1:4 or higher dilution.[50,52] Critical concentrations of antimicrobial drug in serum for other infections have not been established but are generally targeted at concentrations that are severalfold higher than the MIC.

Studies are needed that evaluate the relationship between circulating concentrations of the drug and response to therapy. As with documentation of infection, interpretation of these data is important. Fever, other signs of inflammation, and even hematologic abnormalities can result from the therapy (drug-induced fever, leukocytosis) and nonspecific factors and may not be caused by infection.[10,70] Monitoring is the only means of determining clinical applicability of results of susceptibility tests in vitro and efficacy of the treatment used. Disparity between results in vitro and those in vivo is not uncommon.[3,52,53,56,57,64]

45.7

PRINCIPLE 6: INVESTIGATE CAUSES OF THERAPEUTIC FAILURE

Failure of treatment can result from any of several factors (Box 45-3). When response to treatment is not as expected, the cause should be sought, and the problem should be corrected. Potential for therapeutic failure can be decreased by applying principles outlined in this chapter, by considering the status of the host's defenses, by initiating appropriate treatment before the condition becomes irreversible, and by providing appropriate adjunctive therapy with drugs or by lavage, drainage, or removal of foreign bodies from the site of infection. Conditions caused by bacteria will not respond to antiparasitic drugs; those caused by viruses, helminths, or fungi will not respond to antibacterial drugs; those caused by helminths will not respond to antifungal drugs. These examples serve to demonstrate inappropriate choice of drug, but equally inappropriate is the use of drugs to which the organisms are resistant, that are ineffective in the microenvironment, or that do not distribute to sites of infection. Occasionally an infection that does not respond may be overcome by changing the dose of drug being used, the formulation, the route of administration, or the administration interval or by prolonging the duration of treatment. 1513
Compliance with the selected dosage regimen is necessary before therapeutic success can be expected. Studies 1514
have revealed that inadequate compliance is commonly encountered.[3,57,71] Disease can alter host-related factors such as function of organs, perfusion, or inflammatory response, which affect absorption, distribution, biotransformation, and/or elimination of the drug. Because antimicrobial drugs act in concert with the host's defense mechanisms, any defect in these defenses can reduce the efficacy of antimicrobial drugs. A microenvironment that is inappropriate for activity of the drug, organisms that are resistant to the selected drug, or superinfection may also result in therapeutic failure. Interactions of drugs in vivo or in comixtures can alter pharmacokinetic variables of drugs or render them chemically ineffective. Direct toxicity of antimicrobial drugs can be detrimental to the patient, as well as cause therapeutic failure. If the patient's condition has advanced to a point of irreversibility, any amount of appropriate therapy may be ineffective. Therapeutic failure is too frequently blamed on an inactive or “bad” drug. This is probably the least common cause of therapeutic failure if dates of expiration and conditions of storage of the drug are properly observed and if the product is appropriately used as prescribed.

45.7.1

Box 45-3 Causes of Therapeutic Failure

Inappropriate diagnosis

Inappropriate drug

Inappropriate dosage regimen

Inappropriate absorption, distribution, biotransformation, or elimination of the drug

Impaired host's defense mechanisms

Inappropriate microenvironment

Development of resistance to the drug

Inadequate compliance with the dosage regimen

Superinfection

Interactions of drugs

Irreversible condition of the patient

Toxicity of the drug

Inactive drug

PRINCIPLE 7: RESTRICT CONCOMITANT USE OF ANTIMICROBIAL DRUGS

Fixed-drug combinations or concomitant use of two or more antimicrobial drugs is occasionally appropriate, as shown in Box 45-4.[10,52,53] However, in most instances one drug with a specific antimicrobial spectrum will provide adequate therapy and will reduce the potential of adverse effects in the patient or the potential for selection of resistant organisms. There are very few, if any, situations in which some fixed-drug combinations are superior to individual drugs. When used concomitantly against a specific organism or organisms, two or more antimicrobial drugs may be synergistic, additive, antagonistic, or indifferent in their effect. Selection of two or more antimicrobial drugs for concomitant use should not be undertaken without considering their cumulative effects and the legitimate need for concomitant use of drugs. Too frequently, antimicrobial drugs are combined or used concomitantly to provide “broad-spectrum coverage” because of the attending veterinarian's diagnostic insecurity or to replace diagnostic procedures. Concomitant use of antimicrobial drugs should be limited to the following: to provide synergy against infecting organisms, to prevent bacterial resistance to antimicrobial drugs, to extend the antimicrobial spectrum as part of the initial therapy against life-threatening conditions, or to treat mixed-bacterial infections. Concomitant use of antimicrobial drugs beyond these situations is not justified, unnecessarily exposes the patient to risks of adverse reactions to drugs, and increases pressure for development of resistance to drugs by the infecting organism or others.

45.8.1

Box 45-4 Concomitant Use of Antimicrobial Drugs

45.8.1.1

Potentially Beneficial

Penicillin + aminoglycoside

Cephalosporin + aminoglycoside

Erythromycin + rifampin

Lincomycin + spectinomycin*

Trimethoprim + sulfonamide

Penicillin + sulfonamide

Tetracycline + sulfonamide

Penicillin + clavulanic acid

45.8.1.2

Undesirable

Penicillin + tetracycline

Chloramphenicol + erythromycin

* Potentially lethal complications may develop in horses or sheep that receive lincomycin.

Synergy results when antimicrobial activity of two drugs in combination is greater than would be expected by the sum of the activity of the individual drugs. Synergy can result if the drugs act at different sites in the same metabolic pathway (e.g., trimethoprim + sulfonamide) or at different sites (e.g., 30S and 50S ribosomal subunits) in the organism. Activity of one drug may improve the entry of another drug into the organism (e.g., penicillin or cephalosporin + aminoglycoside) or prevent the degradation of another drug by the organism (e.g., amoxicillin + clavulanic acid). Synergistic combinations of antimicrobial drugs may be essential in some severe infections that are difficult to eradicate or infections in patients with temporarily impaired defense mechanisms. However, concomitant use of antimicrobial drugs is not necessary in routine treatment of most infections. Synergy does not imply that a “better” clinical response will result. Despite evidence of synergy between two drugs in vitro, convincing evidence that such synergistic combinations are superior to single drugs in vivo when treating defined infections is sadly lacking in veterinary medicine. Controlled, prospective clinical investigations designed to evaluate synergistic responses in vivo are desperately needed.

Antagonism has been demonstrated between penicillin and tetracycline.[10] In some instances, ampicillin and chloramphenicol have been antagonistic, whereas in other instances they have been therapeutically beneficial. Antimicrobial drugs that have the same or an anatomically proximate site of action (phenicols, macrolides, and lincosamides) should not be used concurrently because of antagonistic competition for those sites in bacteria.

If bacterial resistance to drugs occurs by mutation and with separate frequencies for two different antimicrobial drugs, the statistical probability that mutational resistance against both drugs will develop is inversely related to the product of the individual frequencies. Following this rationale, concomitant use of antimicrobial drugs has been most successfully applied in the treatment of infections caused by organisms in which resistance to single drugs develops rapidly. Resistance against multiple drugs that is encoded by plasmids should not be expected to follow this pattern. Data fail to support the popular belief that such a combination of drugs is necessary to avoid the development of resistance when there is evidence that resistance forms in face of this concomitant use. The popularity of combination treatments does not necessarily mean they are more efficacious than single-drug treatments.

It is justifiable and recommended to use more than one antimicrobial drug as initial treatment of life-threatening infections before results of bacterial cultures are known. This treatment should be based on the presumption that most, if not all, organisms that cause the infection will be susceptible to selected drugs and that withholding treatment will most likely result in death of the patient. Because such therapy is initiated before the causative agent and its susceptibility can be ascertained, it is imperative that all appropriate diagnostic samples be obtained before initiation of such treatment. It is important that historical or statistical data be taken into account when selecting the most probable causative agent(s). After the infectious agent and its susceptibility are known, treatment should be appropriately adjusted. Extended antimicrobial spectrum is too often abused as a substitute for collection of diagnostic data, because of the veterinarian's diagnostic insecurity or because of the client's insistence on treatment of the patient.

1514

1515

45.9 PRINCIPLE 8: APPROPRIATELY ATTEND TO ADVERSE REACTIONS TO DRUGS

Adverse reactions to drugs can develop in patients as a result of drug-related or host-related factors.[10,70,72] Most can be classified as side effects of the drug, hypersensitivity to the drug or its metabolites, interactions of two or more drugs in vivo or incompatibilities in an admixture before administration, alterations of indigenous microflora by the drug, and direct toxic effects of the drug on the host's tissues or as idiosyncratic or idiopathic reactions that defy elucidation and classification.

Adverse effects are not always predictable and may not be side effects of the drug. Side effects of a drug are usually predictable because they result from the pharmacologic activity of the drug. For example, tetracycline may be selected primarily for its activity against a respiratory pathogen in a foal. Discolored dental enamel on permanent teeth may be an acceptable side effect, but altered intestinal microflora and fatal diarrhea are adverse effects.

All types of hypersensitivity reactions can occur in response to drugs. Clinical signs demonstrated by animals with hypersensitivity reactions to drugs are typical of those caused by other allergens. Because the molecular weight of most drugs is too small for the parent drug to serve as an allergen, polymers of the drug or its metabolites chemically combine with amino acids, polypeptides, or carbohydrates to form allergenic complexes. Polymers alone may be large enough to be allergenic. Figures regarding the frequency and type of hypersensitivity reactions in animal patients may not be representative because reports of such reactions are probably not complete. In the United States, adverse reactions to a drug in animal patients should be reported to the manufacturer of the product

and to the FDA-CVM. It is my opinion that the manufacturer should be the first to be contacted. Manufacturers are the primary resource for data related to their products and are usually equipped and staffed to respond to emergency clinical situations that may result from adverse reactions.

Table 45-2 Specific Drugs and Additives That Are Incompatible When Comixed Before Administration[72,73]

Drug	pH	General Comments	Incompatibilities
Aminophylline	8–9	Not stable if pH <8	Cephalothin Na, tetracyclines, polyionic fluid solutions, penicillin G, morphine sulfate, erythromycin gluceptate, methylprednisolone Na succinate, multiple vitamin solutions, thiamine
Ammonium chloride	4.5–6		Chlortetracycline, sulfadiazine, sulfisoxazole
Ampicillin sodium	8.5–10	Do not mix with other medication because of pH changes	
Calcium chloride	6–8.2		Cephalothin Na, chlorpheniramine, hydrocortisone or prednisolone phosphate, kanamycin sulfate, tetracyclines, sodium bicarbonate (concentration dependent)
Calcium disodium EDTA	6.5–8		Dextrose solutions, tetracyclines
Calcium gluconate	6–8.2		Cephalothin Na, tetracyclines, prednisolone phosphate, sodium bicarbonate, phenylbutazone, sulfonamides
Carbenicillin disodium	6–7		Tetracyclines, aminoglycosides
Cephalothin sodium	5.2	pH <4 or >7	
		Not advised; do not mix with other medication	
Cyanocobalamin (vitamin B_{12})	4–5.5		Alkaline solutions, ascorbic acid, vitamin B complex with C, vitamin K, warfarin
Dexamethasone phosphate	6.5–7		Chlorpromazine
Ergonovine maleate	2.7–3.5		Do not mix with other medications
Erythromycin lactobionate	6.5–7.5	Do not combine with mixtures having a final pH <5	Aminophylline, multiple vitamins, cephalothin Na, pentobarbital, sodium iodide, heparin Na, penicillin G, tetracyclines
Furosemide	8.8–9.3		Acid solutions
Gentamicin sulfate		Do not mix with other medications	

Heparin sodium	5–7.5		Sodium bicarbonate, multiple vitamins, tetracyclines, chlorpromazine or promazine, erythromycin lactobionate or gluceptate, gentamicin SO_4, hydrocortisone sodium succinate, methylprednisolone Na succinate, kanamycin SO_4, meperidine HCl, morphine SO_4, penicillin G (K^+), protamine
Hydrocortisone sodium succinate	7–8		Cephalothin Na, tetracyclines, heparin Na, kanamycin SO_4, multiple vitamins, pentobarbital Na, promazine, erythromycin, tylosin
Kanamycin sulfate	4.5		Cephalothin Na, dextrose, heparin Na, hydrocortisone Na succinate, penicillins, sulfadiazine
Levamisole			Neomycin, phenylbutazone, sulfonamides, tetracyclines
Lidocaine	6–7		Alkaline solutions
Magnesium sulfate	5.5–7		$NaHCO_3$, calcium-containing solutions, tetracyclines
Mannitol	4.5–7		Strongly acidic or alkaline solutions, whole blood, penicillin G
Methylprednisolone sodium succinate	7–8		Aminophylline, heparin Na, tetracyclines, vitamin B
Multiple vitamins			Aminophylline, cyanocobalamin, erythromycin lactobionate, heparin Na, hydrocortisone Na succinate, penicillin G, sodium bicarbonate, tetracyclines
Nitrofurantoin sodium	7.7–9.8		Calcium chloride, insulin, phenol, procaine
Oxytocin	2.5–4.5	Do not mix with other medications	
Penicillin G (K^+ or Na^+)	6–7	Significant inactivation if pH <5.5 or >8	Tetracyclines, acetylcysteine multiple vitamins, vitamin B with C, lincomycin, aminophylline, pentobarbital, thiopental, cephalothin Na, erythromycin, sodium bicarbonate, sulfonamides, heparin Na, gentamicin
Pentobarbital sodium	10–10.5		Acidic solutions, cephalothin Na, erythromycin, tetracyclines, sodium bicarbonate, succinylcholine chloride
Ringer's lactate solution	6–7.5		Epinephrine HCl, tetracyclines, sodium bicarbonate, sulfadiazine Na

Sodium bicarbonate	7–8		Calcium-containing solutions, magnesium sulfate, vitamin B with C, tetracyclines, penicillin G (Na or K), thiopental sodium, pentobarbital Na, streptomycin
Sodium iodide	7.5–9		Vitamin B with C
Succinylcholine chloride	3–4.5		Alkaline solutions, pentobarbital Na, thiopental Na
Sulfonamides	Basic		Acidic solutions, ammonium chloride, gentamicin SO_4, kanamycin SO_4, lincomycin HCl, methicillin, penicillin G, tetracyclines, vitamin B with C, calcium gluconate, dextrose, tylosin, procaine
Tetracyclines	1.8–2.8		Aminophylline, penicillins, magnesium or calcium salts, cephalothin Na, erythromycin, lactobionate, heparin Na, hydrocortisone Na succinate, methylprednisolone Na succinate, multiple vitamins, nitrofurantoin, novobiocin, polymyxin B, lactated Ringer's or Ringer's solution, sodium bicarbonate, sulfonamides, barbiturates
Thiamine (vitamin B_1)	3–4	Neutral or alkaline pH causes decomposition	Iron salts
Thiopental sodium	10–11		Acidic solutions, promazine HCl, sodium bicarbonate, succinylcholine Cl, atropine SO_4, penicillins, cephalosporins, tetracyclines, hydrocortisone Na succinate
Ticarcillin disodium	6–8		Aminoglycosides
Tylosin			Hydrocortisone, tetracycline, streptomycin, sulfonamides
Vitamin B complex	10–11		Alkaline solutions, cephalothin Na, cyanocobalamin, erythromycin lactobionate, hydrocortisone Na succinate, tetracyclines
Vitamin B complex with C	3–6.5		Aminophylline, cephalothin Na, erythromycin lactobionate

EDTA, Ethylenediaminetetraacetic acid.

Interactions of drugs in vivo and incompatibilities of drugs in admixtures are possible when more than one drug is used.[72,73] Some interactions and incompatibilities are well known, and references to these data should be available. Pharmacists have considerable reference material to consult, and their input is extremely valuable in these matters. Before drugs are mixed or administered concurrently, interactions and compatibilities should be determined (Table 45-2). In this context, polyionic fluids, vitamins, minerals, and other substances should all be considered as "drugs."

1516

Alterations in indigenous microflora can reduce the effectiveness of natural host defenses, allow superinfection, or alter normal function of some bodily systems. Fibrinonecrotic colitis in horses that receive clindamycin or lincomycin is an example. This problem is serious enough that the use of these drugs is contraindicated in horses. Tetracyclines (especially doxycycline), macrolides, or potentiated sulfonamides can also alter the intestinal bacterial flora and thereby may precipitate potentially lethal diarrhea.[74,75] These drugs may be drugs of choice for treatment of some patients, and the adverse effects considered in context while a strategy for treatment is formulated.

Toxic effects of antimicrobial drugs may not be predictable. Some drugs such as aminoglycosides or amphotericin B have predictable, dose-related toxicities. The ratio of toxic-to-therapeutic concentrations (therapeutic index) of drugs varies with the drug's properties and host-related factors that alter the patient's susceptibility to toxicity of the drug. If a drug with a low toxic-to-therapeutic ratio is chosen to treat an infection, its toxic and therapeutic effects should be closely monitored. If toxicity of a drug is predictable by its circulating concentrations, total amount of the drug administered, or duration of therapy, careful attention should be afforded these values. The greatest difficulty in predicting either efficacy or toxicity is knowing the minimum concentration of the drug that predictably causes each of these effects in the individual patient. Monitoring circulating concentrations of aminoglycosides is an essential aspect of therapy with these drugs because of their potential for causing toxicity and erratic pharmacokinetics in patients.[69,76] Amphotericin B is also predictably toxic, and careful monitoring of its effects is necessary. Toxicity of drugs that require biotransformation for activation or inactivation can be enhanced or reduced by alterations in biotransformation resulting from disease or concomitantly administered drugs. Chondrotoxic effects of fluoroquinolones in adult and young horses is supported by results of some investigations[25,26] and refuted by others.[27–29] Perhaps an equally important question to be answered while trying to resolve discussions of occurrence of that arthrotoxicity is how well the insulted articular cartilage heals. Just as with disease, drug-injured tissue may regenerate and regain healthy function resulting in indistinguishable effects at a later date.

1516

1517

Frequently the true pathogenesis of an adverse effect is not known. It may not be clearly related to the drug or may not have been observed previously. Because drug-related reactions in animals are iatrogenic, reasonable suspicion that a reaction could be drug related should be maintained until proven otherwise. Observations and thoroughness of investigation by the attending clinician remain the best means of establishing the cause-effect relationship of drug-induced reactions. That diagnosis is often arrived at by a process of elimination of other potential causes.

45.10 PROPHYLACTIC OR METAPHYLACTIC USE OF ANTIMICROBIAL DRUGS

Gordon W. Brumbaugh

The medical definition of *prophylaxis* is the prevention of disease.[77] The word is derived from the Greek prefix, *pro,* which signifies before or in front of, and the word *phylaxis,* which means a guarding or protection from infection. Prophylactic use of antimicrobial drugs implies that the medication is administered before exposure to an infectious organism in order to prevent infection. The term *metaphylaxis* is also of Greek origin, with the prefix *meta* meaning after, beyond, or over. The prefix indicates change, transformation, exchange, after, or next. Metaphylactic use of antimicrobial drugs implies timely administration of the medication after exposure to an infectious organism, during the transformation or development of clinical signs of the disease, before clinical disease is apparent. In previous editions of this text, no distinction between prophylactic use and metaphylactic use of antimicrobial drugs was made. That has been corrected in this edition.

Despite apparently widespread administration of antimicrobial drugs to prevent disease, prophylactic use of antimicrobial drugs remains controversial and of unproven value in many instances.[77a] Far too frequently veterinarians and lay personnel use antimicrobial drugs prophylactically because of concern over diagnostic accuracy. Although indiscriminate use of antimicrobial drugs to prevent disease should be condemned, prophylaxis can be useful in certain circumstances.[78] Unfortunately these circumstances have not been well defined in veterinary medicine, partly because of difficulties in assessing response to microbial prophylaxis.[79] If a beneficial effect results from prophylactic use of drugs, the therapist is encouraged to repeat their administration when later presented with a similar situation. For example, antimicrobial drugs may be administered to horses with viral upper respiratory disease to prevent secondary bacterial pneumonia. If the horse does not develop pneumonia, it is assumed that the antimicrobial drug prevented bacterial pneumonia. Therefore the next horse that demonstrates signs of upper respiratory disease will receive antimicrobial drugs prophylactically. This is not sound reasoning, nor is it justification for prophylactic use of antimicrobial drugs. That horse may not have developed pneumonia if the antimicrobial drugs had been withheld. Seldom is a determination made about whether a result is "because of" or "in spite of" the prophylactic use of medication.

In some instances, antimicrobial drugs are used prophylactically with guidance by clinical impressions. Unfortunately, objective data to support such uses are not always available. Controlled, blinded, prospective clinical investigations are of paramount importance for obtaining that information.[79] Proper performance of such studies can be difficult. The multitude of factors involved with such studies (e.g., large numbers of patients, criteria for selection of patients, confirmatory diagnostic procedures, choice of "appropriate controls," variables to be evaluated, dosage regimens, and ancillary measures to be used) result in a complexity that discourages most veterinarians who initially desire to embark on such studies. An additional factor that complicates studies of the efficacy of antimicrobial drugs perioperatively is that historical incidences of infection may not be reliable controls because surgical techniques vary among surgeons and have changed because of advances in surgical materials and procedures. Therefore prophylactic use of antimicrobial drugs in many situations remains a matter of opinion, risk, and concern based on conditions pertaining to the individual patient rather than a matter of fact that is universally applicable. Consequently, recommendations for prophylactic use of antimicrobial drugs should not be dogmatic.

However, principles for prophylactic use of antimicrobial drugs in each situation are the same. Antimicrobial drugs are occasionally used in animals to prevent coccidiosis, clostridial infection of wounds, bacterial pneumonia, and bacterial infections after orthopedic or intraabdominal surgical procedures. Morbidity and mortality associated with coccidiosis was reduced in susceptible calves by preexposure administration of monensin.[80] The incidence of clostridial infections in untreated wounds is not accurately known. Specific immunity in the host, complicating factors, use of biologics, and ancillary procedures influence the incidence and severity of such infections. Because clostridial organisms produce severe and often lethal infections, the risk of fatal vegetative infection warrants the prophylactic use of antimicrobial drugs in high-risk patients. However, antimicrobial drugs should not be considered a substitute for active immunization provided by biologic products or for proper local treatment of the wound.

Antimicrobial drugs used prophylactically are perhaps used most to prevent or control bacterial pneumonia. It has been stated that viral respiratory diseases predispose the respiratory tract to secondary bacterial infections. Concerns that viral infections predispose the entire respiratory tract to bacterial infection are based on the fact that the former can destroy ciliated epithelium and inhibit mucociliary clearance mechanisms, reduce production of surfactant, promote virulence of bacteria, and inhibit phagocytic activity against some bacteria.[81–84] But the

efficacy of antibacterial mechanisms in preventing bacterial superinfections appears to depend on the bacteria and the virus(es) involved.

All viral pneumonias do not result in bacterial superinfections; conditions must be appropriate for that to occur.[82] One investigator proposed that the secondary bacterial infection of the upper respiratory tract was probably "beneficial in the total infection experience" of the young horse entering training or racing.[85] In spite of these data the true incidence and risk-related factors surrounding secondary bacterial infections are not known. Several controlled prospective studies have evaluated metaphylactic use of antimicrobial drugs against respiratory disease in cattle. Similar, but limited, studies performed with horses have shown that some transported horses may benefit from prophylactic use of antimicrobial drugs.[86]

Control of bovine respiratory disease complex (BRDC) with antimicrobial drugs in cattle at high risk for developing the disease has been studied intensely for several years.[87–98] Nevertheless, effects of metaphylactic use of antimicrobial drugs in BRDC and recommendations for such use are far from universal. Many factors contribute to the incidence of BRDC: vaccination history of the animals, environment, diet, duration of shipment, time of initial medication after arrival, number of calves per group, commingling of animals from different sites of origin, condition of the calves, method of administration of medication (by injection, in water, or in feed), duration of administration, and sequence of administration if more than one antimicrobial drug was used.

Many factors can complicate assessment of metaphylactic use of antimicrobial drugs against BRDC, but efficacy of control of BRDC can be evaluated by several variables that include morbidity, mortality, epidemiologic pattern of morbidity and mortality, days of treatment, amount of medical attention required (labor and medication), weight gain, relapses, and/or economic return.[87,89,91,93–96,99]

Metaphylactic use of antimicrobial drugs can be beneficial, but it is unrealistic to expect total elimination of disease. Control or management of a disease and its effects would be a more realistic expectation. The effect desired from prophylactic or metaphylactic use of drugs must be specifically understood. Reduced morbidity or mortality, reduced severity of clinical signs, reduced duration of therapy, improved growth rate, improved feed efficiency, and improved or maintained production may be benefits of metaphylactic use of antimicrobial drugs, but false confidence in prevention of disease should be avoided. Volatility of costs associated with production and the market probably influences profit more than does the cost of metaphylactic use of antimicrobial drugs.

Ambiguity of antimicrobial prophylaxis or metaphylaxis in equine medicine is supported in part by a review of reports of experimentally induced as well as naturally occurring equine rhinopneumonitis and equine influenza. Equine herpesvirus 1 produces viral bronchopneumonia[100] and interstitial pneumonia.[101] Serous to mucopurulent rhinitis was observed commonly and was similar with equine influenza.[81,85,100–106] Secondary bacterial infections were confined to the upper respiratory tract (i.e., rhinitis, lymphadenopathy) and did not include bacterial pneumonia.[99,102,104,105]

Perioperative use of antimicrobial drugs prophylactically is a common practice. In human patients, such use has proven to be of benefit in prosthetic cardiac valvular operations, gynecologic surgical procedures, and gastrointestinal operations.[79] The drugs were administered orally, systemically, or topically as indicated by the procedure. A study with 122 dogs and seven cats undergoing elective, clean surgical procedures revealed no significant difference in incidence of infection between a group that received ampicillin and a group that received a placebo.[107] Similar studies with horses are not known to the author at this time. Principles for prophylactic use of antimicrobial drugs perioperatively are similar to those outlined here. Principles for timely metaphylactic use of antimicrobial drugs have been proposed and are similar to those listed for prophylaxis.[87]

When antimicrobial drugs are used prophylactically, several principles should be followed.[77a–79,108–111]

1 The relative risk of infection must be sufficient to warrant the use of antimicrobial drugs prophylactically. Risks associated with the prophylactic medication must be less than risk of development of the disease and consequences of that disease. Risk of infection is related to virulence of the organism, amount of exposure (size of inoculum and duration), and the host's defense status. All these factors should be considered before antimicrobial drugs are used prophylactically. “Sufficient risk” is difficult to clarify because of numerous factors used to assess risk. Mortality or morbidity, severity of the disease, duration of the disease, or the effects of the disease on production or performance may be considered unacceptable in some situations if prophylaxis is not implemented. However, risks and costs of the prophylactic medication must also be considered. There are few epidemiologic data from which to accurately predict these risk factors; therefore they must be assessed on an individual basis. The primary potential advantage of prophylactic use of antimicrobial drugs is prevention of infection, but other advantages are also possible and include decreased morbidity and/or mortality, decreased duration of treatment if infection subsequently occurs, decreased severity of disease, shortened convalescence, improved or maintained production, and decreased cost of overall effects of disease. Potential disadvantages of prophylactic use of antimicrobial drugs include alteration of resident bacterial flora, development of resistant organisms, superinfection, delayed onset of infection, relaxed attention to diagnostic details, adverse reactions to the drug(s), and increased overall cost of therapy.

2 The organism(s) that is likely to cause infection and its antimicrobial susceptibility should be known or accurately predicted. Just as biologic products are used prophylactically to stimulate specific active or passive immunity, prophylactic use of antimicrobial drugs should be directed at a specific pathogen rather than at all possible organisms. It is difficult to anticipate all possible infectious organisms that are likely to be encountered, but agents that cause some diseases are reasonably predictable. It is preposterous to expect sterilization of the site of potential infection. The antimicrobial susceptibility of the pathogen should be consistently predictable on the basis of historical data. Clostridial and streptococcal organisms are not as predictably susceptible to penicillin as they were in years past. The susceptibility of gram-negative, aerobic organisms is not reliably predictable, and resistance develops frequently when these bacteria are continuously or intermittently exposed to antimicrobial drugs. Anaerobes are predictably susceptible to penicillin G, chloramphenicol, metronidazole, or lincosamides.[112] Lincosamides should not be used systemically in horses; chloramphenicol and metronidazole are prohibited in the United States for administration to animals that are used for human consumption. *B. fragilis* produces β-lactamase, rendering 1518
those organisms resistant to penicillins. Aminopenicillins and cephalosporins that are classified as greater 1519
than first-generation have less predictable activity against anaerobes than does penicillin G.[113]

3 For effective prophylaxis the drug must be administered and must distribute to the site of potential infection before contamination or the onset of infection and should at least reach inhibitory concentrations. For effective metaphylaxis, the drug should be administered after exposure to the organism, with sufficient time for the medication to act on those organisms before clinical signs develop. In those clinical situations a rational basis for use of antimicrobials is formed by the attending veterinarian, who is well acquainted with the production system, the profile of the animals, and the diseases present or likely to develop that threaten the health of the animal(s). After infection is established and clinical signs are apparent, the use of the antimicrobial drug becomes therapeutic, not prophylactic or metaphylactic. Therefore the time of exposure or contamination with a pathogen, incubation time of the pathogen, and distribution characteristics of the selected drug should be considered in order to administer an antimicrobial drug prophylactically or metaphylactically and in a timely manner.

4 As much as possible, drugs used prophylactically should not be those that would be used therapeutically if an infection develops. If infection develops during the prophylactic regimen, an alternative treatment must be formulated, because if the disease is not prevented by an appropriate dosage regimen with the drug, it will not be cured by the drug. If that infection is caused by induced resistance to the selected drug, therapy could be compromised if that drug is the therapeutic drug of choice. The population of resistant organisms poses risks of increased incidence of refractory infections in other animals as well.

5 The duration of antimicrobial prophylaxis should be as abbreviated as possible (e.g., 3 to 6 hours postoperatively). Generally, little benefit can be gained beyond 24 to 36 hours postoperatively. If exposure to infectious organisms is brief and host defenses are functional, prolonged administration of the drug is not necessary. However, there are a few indications for prolonged prophylactic therapy. If host defenses are temporarily deficient or if exposure is prolonged, administration may need to be extended. The duration of administration should be directed by the same factors that direct the duration of therapeutic use of drugs (i.e., activity of the host's defenses, ability of the organism to resist those defenses, mechanisms by which the organism develops resistance to the drug(s), location of the infection, and primary activity of the drug against the organism).

6 No drug can be used without risk of adverse reactions, but antimicrobial drugs used prophylactically should present minimal risk of adverse effects. Deleterious reactions may occur when drugs are administered. It is better to abstain from using drugs than to use them inappropriately.

7 Theoretically the selected dosage regimen should provide bactericidal rather than bacteriostatic concentrations of the drug at the site of infection. It would be desirable to kill the pathogen rather than to inhibit its growth; however, no data clearly show this is necessary in clinical situations.[56] Host defenses, subtherapeutic concentrations of the drug, and postantibiotic effects, as well as ancillary management, should be used to enhance the efficacy of drugs in vivo.

Decisions about prophylactic use of antimicrobial drugs are not easily made and are usually based on logic and analogous situations.[78] Classification of clinical circumstances and diseases of human patients has been proposed as an aid to such decisions for that species. That classification considers the risk of developing infection based on function of the patient's natural defenses, duration of exposure to pathogens, and potential for infection by either one or multiple organisms. Direct application of that classification system to animal patients may be difficult.

Assessment of some defense mechanisms in domestic animal patients is complicated and beyond routine use in many clinical situations. Some pathogens are noted for their ability to temporarily compromise the host's defenses, yet effects of others are unknown. Methods that are applicable (e.g., determination of concentrations of immunoglobulins, numbers and function of phagocytes and of lymphocytes) should be used when indicated and when appropriate medical management is determined. However, numbers of cells do not equate with function, and concentrations of immunoglobulins do not equate with specific activity. Animal patients must convalesce in an environment that is less hygienic than that of human patients. Animals are constantly exposed to many primary and opportunistic pathogens (bacteria, viruses, fungi, parasites) and intermittently exposed to individual pathogens that cause diseases of epizootic proportions. Therefore criteria for classification by risk of infection and indications for prophylactic use of antimicrobial drugs in animals need to be developed from epidemiologic studies of diseases of animals and controlled clinical investigations. At this time, that information is sadly lacking.

Except in specific instances with specific goals in mind, the use of antimicrobial agents to prevent infection has not been as valuable as the therapeutic use of antimicrobials. Prophylactic use of antimicrobial drugs must be

tailored to the specific needs of each individual patient, as determined by the attending veterinarian and tempered by application of the principles outlined here.

45.11 EXTRALABEL USE OF MEDICATIONS IN FOOD ANIMALS

Michael Payne

In 1994 the Animal Medicinal Drug Use Clarification Act (AMDUCA) was signed into law, amending the Food, Drug, and Cosmetic Act and legalizing most instances of extralabel use of drugs (ELUD) by veterinarians.[114] For food animal practitioners, with this privilege comes the weighty responsibility of protecting the health of consumers of animal products. Veterinarians must meet very specific conditions before they may legally use or prescribe drugs in an extralabel fashion. Extralabel drug uses include prescribing or administering a human or veterinary drug at a higher dose, frequency, or duration, by a different route of administration, in a different species, or for a different indication than as described on the product's label. ELUD is limited to cases in which the health of the animal is threatened or when suffering or death may result from a lack of treatment. ELUD may not be used to enhance production or for reproductive cycle manipulation in normal animals. ELUD may be considered in food-producing animals only when no approved drug is available that contains the same active ingredient in the required dose, form, and concentration or when the veterinarian finds that there is no approved drug that is clinically effective for the intended use. Extralabel drug use in or on animal feed is also expressly prohibited. Veterinarians' obligations regarding extralabel use are listed in Box 45-5. Veterinarians violating state or federal laws regulating the transport, sale, or use of drugs may face a variety of sanctions including warning letters, fines, temporary or permanent revocation of license, and incarceration.

1519

1520

45.11.1 Box 45-5 Conditions Necessary for Extralabel Use of Drugs

1. Extralabel use of drugs (ELUD) is permitted only by or on the order of a veterinarian.
2. The veterinarian judges on-label treatments to be unavailable or ineffective.
3. ELUD uses only U.S. Food and Drug Administration (FDA)–approved animal and human drugs, not drugs imported from foreign countries or compounded from bulk sources.
4. A valid veterinarian-client-patient relationship (VCPR) exists in which the veterinarian:
   - oversees medical treatment decisions on the farm
   - is familiar with animal care through appropriate and timely visits
   - has sufficient knowledge to initiate a diagnosis
   - is available for follow-up care as needed
5. ELUD is for therapeutic or humane purposes only, not to increase production or manipulate reproductive cycles in normal animals.
6. ELUD applies only to administration to individual animals and in water, not in feed.
7. Animal identification and treatment records are sufficient to identify treated animals and their treatment history and are maintained for 2 years.

8 The veterinarian establishes an extended drug withdrawal period protective of human health supported by scientific evidence. ELUD resulting in violative or dangerous food residues is not permitted.

9 Drug labels list the name and address of the prescribing veterinarian, animals to be treated, and the drug name, disease indication, dose, frequency, duration, cautions, and withdrawal periods associated with treatment.

10 Certain extralabel uses specifically prohibited by the FDA are not used (Box 45-6).

45.12 DRUGS PROHIBITED FROM EXTRALABEL USE IN FOOD ANIMALS

Certain drugs may not be prescribed or used even under the auspices of AMDUCA.[115] Under statutory authority provided in AMDUCA, the FDA's Center for Veterinary Medicine (CVM) has prohibited approximately a dozen drugs or drug classes, making their extralabel use in food animals illegal. Other compounds not specifically listed in AMDUCA are prohibited by virtue of the fact that no approved animal or human products are commercially available. Lastly, extralabel use of treatments is also regulated by the Pasteurized Milk Ordinance (PMO). The extralabel use in food animals of the compounds listed in Box 45-6 represents one of the FDA's highest priorities for regulatory attention.

45.12.1 Diethylstilbestrol

From the 1940s to the 1970s U.S. physicians prescribed diethylstilbestrol (DES, a potent nonsteroidal synthetic estrogen) to pregnant women to prevent miscarriage and other reproductive diseases. In 1971 a link between in utero exposure to DES and a rare vaginal cancer (clear cell adenocarcinoma) was established. In the same year the FDA published an alert advising doctors against the use of DES during pregnancy. The U.S. Department of Agriculture (USDA) banned the use of DES in food animals in 1979.

45.12.1.1 Box 45-6 Drugs or Drug Classes Prohibited from Extralabel Use of Drugs*

Diethylstilbestrol (DES)

Chloramphenicol

Nitroimidazoles (including dimetridazole, metronidazole, and ipronidazole)

Sulfonamide (other than sulfadimethoxine) in adult dairy cattle†

Clenbuterol

Fluoroquinolones (e.g., enrofloxacin and danofloxacin)

Glycopeptides (e.g., vancomycin)

Nitrofurans (including nitrofurazone, furazolidone; topical use prohibited as well)

Phenylbutazone in adult dairy cattle*

Adamantidine and neuraminidase inhibitors in poultry

* Extralabel use of some drugs or drug classes (not specifically addressed in the Animal Medicinal Drug Use Clarification Act) are prohibited because these drugs are not available as approved animal or human products, by U.S. Food and Drug Administration (FDA) policy or in the Pasteurized Milk Ordinance (see text).

† Defined by FDA as dairy cattle (lactating or dry) older than 20 months of age.

45.12.2 Chloramphenicol

An estimated one in 10,000 to 50,000 people exposed to chloramphenicol will develop a non—dose-related aplastic anemia. Because of concerns that this idiosyncratic and frequently fatal complication could be triggered by residues, chloramphenicol use in food animals was prohibited in 1984. The prohibition extends to all formulations of chloramphenicol including ophthalmic ointments. Florfenicol, a synthetic member of the chloramphenicol family, lacks the p-NO2 group thought to be responsible for inducing the aplastic anemia. Florfenicol may be used extralabel in food-producing species.

45.12.3 Nitroimidazoles

Historically, dimetridazole and ipronidazole have been approved for the treatment of histomoniasis (infectious enterohepatitis, blackhead) in turkeys. Ipronidazole and the human drug metronidazole have been used off-label to eliminate the carrier state of trichomoniasis in bulls. Laboratory studies of members of this drug class demonstrated mutagenicity and carcinogenicity, leading to the prohibition of their use in food animals. Because there are no approved veterinary nitroimidazole labels, the use of any member of this drug class in food animals is illegal.

45.12.4 Sulfonamide in Adult Dairy Cattle

The observed carcinogenicity of sulfonamides in laboratory animals, coupled with frequent finding of sulfonamide residues in milk, led to the prohibition of extralabel use of these compounds in adult dairy cattle. The FDA defines a lactating cow as any dairy cow (milking or dry) older than 20 months of age. Only one sulfonamide has a label for dairy cattle, sulfadimethoxine (SDM). The use of any sulfonamide other than SDM in adult dairy cattle is illegal. In addition, extralabel use of SDM in lactating dairy cattle is prohibited. This would include use of a higher dose of SDM or using slow-release formulation SDM boluses.

45.12.5 Nitrofurans

In the past, nitrofurazone and furazolidone were approved for a variety of protozoal and bacterial infections in poultry and swine. Topical formulations (sprays and "puffer" products) have also historically been marketed for wounds and ocular infections in livestock ("pinkeye"). Based on laboratory evidence of carcinogenicity and the absence of a reliable detection method, the FDA withdrew approval for systemic animal nitrofuran products in 1991 and prohibited all extralabel treatment (including topical use) in 2002. Because nitrofurans have no approved food animal uses, the use of any member of this drug class in food animals is illegal.

45.12.6 Clenbuterol

Marketed in the United States as an equine bronchodilator, this synthetic sympathomimetic has been used illicitly to increase weight gain and lean body mass in food animals, particularly show animals. Because muscle depletion and fat redeposition commences after drug withdrawal, producers may be tempted to market animals with little or no withdrawal interval. Cooking temperature only minimally denatures the compound, and toxicity from residues has resulted in hundreds of emergency hospitalizations in European consumers.

45.12.7 Fluoroquinolones

Uncertainty exists related to the magnitude and significance of human pathogen resistance resulting from antibiotic use in animals. Fluoroquinolones are mainstay treatments of antibiotic-resistant *Salmonella* and anthrax infections in humans. Concern that fluoroquinolone use in food animals was promoting human pathogen resistance prompted CVM in 1997 to prohibit extralabel use of these compounds. Any deviation from a fluoroquinolone product label (altering species use, dosage, route of administration, or disease indication) is illegal. In the case of the approved beef cattle formulation of enrofloxacin and danofloxacin, this prohibition extends to use in all non—beef-production animals including lactating and nonlactating dairy cows, heifer replacements, bulls, and veal calves.

45.12.8 Glycopeptides

Vancomycin, the only glycopeptide antibiotic available in the United States, is often the therapy of last resort for methicillin-resistant *Staphylococcus aureus* (MRSA) infections in humans. Demonstration of vancomycin-resistant *Enterococcus* in the feces of poultry and swine fed the glycopeptide avoparcin led CVM in 1997 to prohibit extralabel use of glycopeptides in food animals.

45.12.9 Phenylbutazone in Adult Dairy Cattle

The use of phenylbutazone, a nonsteroidal antiinflammatory agent in humans, has been associated with a variety of adverse drug reactions including fatal blood dyscrasias. After USDA reports of a high incidence of phenylbutazone tissue residues in cull dairy cows, CVM prohibited its use in female dairy cattle older then 20 months of age. Antiinflammatory therapy for lactating dairy cattle is available as flunixin meglumine. Flunixin should be used only on-label (intravenously) because intramuscular or intravenous administration can greatly extend withdrawal times.[116]

45.12.10 Antiviral Drugs in Poultry

Concern exists that use of antiviral drugs in poultry could promote drug resistance in zoonotic pathogens, particularly avian influenza H5N1 (“bird flu”). These concerns led CVM in 2006 to prohibit extralabel use of two drug classes used in treating human influenza. Adamantidine and neuraminidase inhibitors may not be used in chickens, turkeys, and ducks.

45.12.11 Dipyrone

Aside from compounds specifically prohibited through AMDUCA, there are several compounds that CVM has reminded veterinarians cannot be legally obtained as finished animal or human products and therefore have no legal extralabel uses.

Dipyrone, used historically as an antipyretic and antiinflammatory, has been associated with teratogenicity and agranulocytosis in humans and cannot be used in food animals.

45.12.12 Estradiol Cypionate

Before 2003 estradiol cypionate (ECP, a synthetic estrogen) was commercially marketed as reproductive therapy in food animals. ECP had not undergone a formal approval process, however, and discretionary marketing was discontinued for lack of food safety and efficacy data. Use in or compounding of ECP for food animals remains illegal.

45.12.13 Hormone Implants in Veal Calves

Although growth-promoting hormone implants have been marketed for ruminating cattle, these products never underwent regulatory approval for nonruminating veal calves. Concern existed in CVM that nonruminating calves may eliminate the hormone contained in the implants differently then ruminants. In 2005 a new warning statement was added to the label of all growth-promoting hormone implants reminding producers and veterinarians that their use in veal calves is illegal.

45.12.14 Dimethyl Sulfoxide and Colloidal Silver

Besides AMDUCA, the Grade A PMO also directs how drugs will be used and stored on dairy farms. Dimethyl sulfoxide (DMSO) and colloidal silver may not be used in or on dairy animals and if found during a dairy inspection can result in “debits.”

45.13 TREATMENT OF COMPANION OR PACK ANIMALS WITH PROHIBITED SUBSTANCES

The prohibitions listed previously pertain to food-producing animals only and not companion species such as dogs and cats. Veterinarians occasionally treat companion animals belonging to a food-producing species (horses, llamas, pygmy goats, pot-bellied pigs). As long as these animals are never offered for slaughter, CVM does not normally consider these to be food animals. Practitioners who have used a prohibited substance in a companion or pack animal that subsequently enters the food supply are subject to enforcement actions under the Food Drug and

Cosmetic Act. In choosing to use a prohibited drug in a companion or pack animal, the practitioner is accepting a certain amount of liability because the ultimate fate of such treated animals is often beyond their control. Practitioners may choose to have owners sign an agreement (entered into the medical record) not to introduce the animal into the human chain.

1521

1522

45.14 EXTRALABEL USE OF MEDICATED FEEDS IN MINOR SPECIES

AMDUCA also prohibits the extralabel use of medications in feed. Generated by concerns of antibiotic resistance, AMDUCA's Section 530.11 specifically prohibits the “extra-label use of an approved new animal drug or human drug in or on an animal feed.” As a matter of enforcement discretion, CVM generally has not objected to mixing a drug with an individual animal's feed, but extralabel mass medication in feed is prohibited “without limitation or exception.”

Veterinarians may, however, be called on to treat minor food animal species such as farmed exotic ruminants, fish, or game birds. CVM has found that for many of these species there exist very few approved drugs. In addition CVM recognizes that some minor food animal species (such as fish and game birds) cannot be practically medicated in any way other than through the use of medicated feeds. In such situations, a veterinarian may determine that extralabel use of medicated feeds (approved for use in other species) can prevent suffering and death in these minor species.

Although AMDUCA prohibits ELUD in feed, in the previously described circumstances CVM “ordinarily will not consider regulatory action” against the veterinarian or animal producer provided that certain criteria listed in Box 45-7 are met.[117] The CVM policy being implemented in these cases is akin to that of extralabel drug use by veterinarians before the 1994 passing of AMDUCA. The drug use is still illegal, but CVM will apply regulatory discretion relative to taking enforcement action.

45.14.1 Box 45-7 Conditions Necessary for Extralabel Use of Medicated Feed in Minor Species

1. Extralabel use of medicated feed is only for treatment of minor species, defined by exclusion as animals other than cattle, horses, swine, chickens, turkeys, dogs, and cats.
2. Extralabel use of medicated feed is limited to farmed or confined minor species but not unconfined wildlife.
3. Extralabel use of medicated feed is limited to situations where the health of an animal is threatened and suffering or death may result from failure to treat.
4. There is no alternative therapeutic dosage form (besides feed) that can be practically used under legal extralabel use.
5. Only feeds formulated and labeled for use in a major species animal are used.
6. Extralabel use of medicated feed in aquaculture is limited to medicated feed products approved for use in aquatic species.

7 The medicated feed is used within 3 months of a veterinarian's written recommendation. Recommendations, feed labels, and invoices are kept for at least 1 year. Adverse reactions are reported to the U.S. Food and Drug Administration within 10 days.

8 All other Animal Medicinal Drug Use Clarification Act requirements are complied with, including a valid veterinarian-client-patient relationship, lack of label alternatives, treatment records, animal identification, and extended withdrawal times (see Box 45-6).

9 The medicated feed is used in accordance with federal, state, and local environmental regulations and approval. This is particularly important for aquaculture uses.

10 The producer has followed worker safety provisions in the approved product labeling.

A critical aspect of CVM's regulatory discretion in this practice is that labeled treatment alternatives are not available. The best resource to aid practitioners in determining what treatments are approved for minor food animal species is the Minor Species Drug Approval site (www.nrsp-7.org).

45.15 COMPOUNDING IN VETERINARY PRACTICE

Compounding is defined as a manipulation to produce a dosage form of a drug other than that provided for in the labeling, such as reconstitution. CVM recognizes the need for compounding within certain areas of veterinary practice, such as mixing or dilution. Because of the absence of safety, efficacy, and food safety data for compounded drugs, potential exists for adverse reactions in treated animals or consumers of their products. Under AMDUCA, it is legal for veterinarians (or pharmacists on the order of a veterinarian) to compound from U.S.-approved animal and human drugs if the conditions listed in Box 45-8 are met.[114,118]

45.16 ANTIDOTES FOR FOOD ANIMALS

For both regulatory and economic reasons, there are relatively few antidotes available to treat cases of toxicity in food-producing species. In most circumstances practitioners treating toxicity in food animals are compelled to use products in an extralabel manner or to compound antidotes from bulk sources.[119] From a regulatory standpoint veterinary antidotes can be placed in one of three categories, discussed in the following paragraphs.

45.16.1 Unapproved Commercially Marketed Veterinary Antidotes

CVM has applied regulatory discretion to allow commercial manufacture and marketing of several compounds that can be used as antidotes, even through they have never completed formal regulatory approval. These are atropine sulfate, epinephrine, and vitamin K.

45.16.2 Antidotes Labeled for Humans Only

There are additional human-label antidotes that can be used off-label under AMDUCA. These include pralidoxime chloride (2-PAM) and dimercaprol (British anti-lewisite or BAL).

45.16.2.1

Box 45-8 Requirements for Compounding in Veterinary Practice

1 No approved animal or human drug can be used in its available dosage form and concentration.

2 Only approved animal or human drugs are used in the compounding, specifically not foreign or bulk drugs.

3 Compounding is performed by a licensed pharmacist or veterinarian in compliance with state pharmacy laws.

4 Adequate procedures are in place to ensure the safety and effectiveness of the product.

5 Withdrawal times are set by the veterinarian and not the pharmacist.

6 The scale of the compounding operation is commensurate with the established practice needs.

7 All other Animal Medicinal Drug Use Clarification Act requirements are met (see Box 45-5).

1522

1523

45.16.3

Antidotes Compounded from Bulk Drug

Several chemicals commonly recommended as food animal antidotes are available only through compounding from bulk drug. As described in the previous section, compounding veterinary medications from bulk drugs is illegal. However, analogous to its policy concerning ELUD in feed for minor species, CVM will not normally consider regulatory action against veterinarians compounding certain antidotes from bulk sources if certain conditions are met, essentially the same as those listed in Boxes 45-5 and 45-8. CVM has listed nine chemical antidotes against which the FDA and CVM would presently not ordinarily object. These include ammonium molybdate, ammonium, tetrathiomolybdate, ferric ferrocyanide, methylene blue, picrotoxin, pilocarpine, sodium nitrite, sodium thiosulfate, and tannic acid.[117,118] This list should not be construed as containing the only drugs for which the FDA would extend regulatory discretion for compounding, and inquiries about additional compounds can directed to the FDA/CVM, Division of Compliance, 301-827-1168. It is critical that veterinarians recognize that in toxicity cases withdrawal periods will need to be established not only for the antidotes but the toxicants as well. For this reason practitioners are advised to consult the Food Animal Residue Avoidance Databank (FARAD) when dealing with cases of toxicosis in food animals.

45.17

FOOD ANIMAL RESIDUE AVOIDANCE DATABANK SUPPORT FOR VETERINARIANS

Consistent regulatory requirements for ELUD (using approved drugs, feed, or compounding) are that approved, effective veterinary drugs are not available and that the attending veterinarian prescribe scientifically valid withdrawal periods before marketing of milk, meat, eggs, or other edible products. Commonly the most efficient way for a food animal practitioner to meet these requirements is to consult FARAD. Veterinarians, producers, students, or regulatory personnel may obtain free consultation with specialists by contacting 1-888-US-FARAD or accessing the FARAD website at www.farad.org. FARAD maintains a database of all food animal products approved in the United States and more then 9000 pharmacokinetic citations describing depletion of more then 2000 chemicals in various species. The FARAD website contains a database of approved food animal drugs searchable by drug, trade name, and species as well as downloadable copies of past published summary recommendations.

46 Chapter 46 Biosecurity and Infection Control for Large Animal Practices

Paul S. Morley

Scott Weese

Infection control, biosecurity, biocontainment, and biosafety are essential functions at all health care operations, including veterinary practices.* All veterinarians at some level recognize and act to prevent adverse outcomes in patients. However, as major outbreaks of nosocomial infections at veterinary hospitals have become more publicized[1–11] it has become increasingly apparent that coordinated infection control practices are a critical component of delivering high-quality care at veterinary facilities, especially those with large case loads and those that specialize in intensive care of patients. The standard of veterinary care is changing such that sporadic occurrences and outbreaks of nosocomial infections may no longer be interpreted as unavoidable accidents if coordinated measures are not routinely used to minimize their likelihood. Our understanding about infection control issues in veterinary medicine has also advanced significantly during the past decade. What may have passed as sufficient for infection control in veterinary practices 10 or 20 years ago may not be sufficient today. It is also important to realize the important part that infection control and biosecurity must play in ambulatory practices and on our clients' premises. Inherently, healthy animals with lower contagious disease risks represent a smaller proportion of hospital populations than they do among populations in their home environments. However, veterinarians are obviously called on to contact those animals most likely to be shedding contagious pathogens regardless of whether this is in hospitals or in the field. In addition, we are aware of several examples in which patients discharged from hospitals were the likely source of viral and bacterial infections in animals in their home environments. Therefore it is also true that the need to apply sound biosecurity and infection control practices extends well beyond the walls of veterinary hospitals. Although the discussions in this chapter are mostly framed in the context of hospital settings, the concepts and issues apply much more broadly to ambulatory practices and animals' home premises.

46.1 HOW MUCH IS ENOUGH? HOW MUCH IS TOO LITTLE?

Just as nobody can tell someone how much health insurance or how much fire insurance for a home is enough, it is not possible to define a correct or best level of risk aversion, and there are no absolute determinants of whether one specific biosecurity action is necessary or superfluous. Although it may not be possible to judge whether a veterinary practice is employing too much biosecurity, a more critical concern must be whether there is too little effort being expended in infection control. Exposures to contagious disease threats, nosocomial infections in patients, and zoonotic infections in care providers are all undeniable risks in every veterinary practice. Because veterinarians have an ethical and legal obligation to take reasonable protective actions to prevent their patients and employees from foreseeable harm associated with their actions (and inactions), it is therefore undeniably possible to not pay enough attention to infection control.

Recognition of these risks undoubtedly gives reason for pause, but a better motivation regarding infection control should be to provide the best veterinary care possible (within the scope of a veterinary practice's specialization). In order to create an environment in which patient care can be optimized, it is incumbent on veterinarians to actively manage the risk of nosocomial infections in their patients. Achieving excellence in patient care and helping clients are undoubtedly among the highest priorities for all veterinary practices. However, the occurrence of nosocomial infections in our patients is an ever-present hazard that interferes with our ability to deliver optimal patient care. *Good infection control practices are not the only feature defining excellence in veterinary care, but it is impossible to achieve excellent patient care without employing logical infection control procedures.* The

implications of suboptimal infection control practices may not always be readily apparent, but both sporadic infections and outbreaks can have a significant effect on patient morbidity, patient mortality, hospital economics, personnel health, personnel morale, and facility reputation. There are also potential liability implications for nosocomial infections that occur in the absence of a proper infection control program.

Although nosocomial infections are an undeniable hazard associated with caring for patients, and although it is possible to reduce the risk of infections through a variety of prevention strategies, it is important to note that not all nosocomial infections are preventable using practical and cost-effective control programs. For such programs to be most successful, it is important that over time administrators and personnel responsible for infection control programs strive to better understand and target prevention efforts at the preventable fraction of all nosocomial infections.

1524
1525

* Throughout this chapter the terms *infection control* and *biosecurity* are used interchangeably to encompass all practices related to the prevention of introduction and spread of infectious diseases in populations of animals or their human caregivers. Some authors differentiate activities by using the term *biosecurity* to specifically refer to issues related to disease introduction and differentiate this from *biocontainment,* which may focus more on control of the spread of agents after introduction. In addition, the term *biosafety* is sometimes used to specifically relate to matters pertaining to human health.

46.2 PRINCIPLES OF INFECTION CONTROL

In general, all comprehensive infection control programs center on three major activities: decreasing the likelihood of exposing patients to infectious agents, maximizing participation of personnel in infection control activities, and optimizing the efficiency of infection control procedures and policies.

When initiating an infection control plan, it is important to take a global assessment of the contagious disease hazards in your practice, your level of risk aversion, and the resources that can be expended on infection control efforts. If a veterinary practice predominantly works in preventive health care under extensive field conditions, the contagious disease hazards may be less common and less severe than those encountered if a practice concentrates on intensive care of patients in a hospital. The specific disease hazards will also vary with the types of patients being managed (e.g., sick neonates vs. patients with acute gastrointestinal disorders vs. reproduction cases, equine vs. bovine vs. camelid, and so on). Risk aversion is a concept that relates to how much a person or business is unwilling to accept a negative event or allow it to occur. The inverse of risk aversion can be thought of as risk tolerance. The more risk averse a person is, the more it may be reasonable for him or her to initiate and maintain a rigorous infection control program. In contrast, a more risk-tolerant veterinarian may recognize the potential for contagious disease hazards in the practice but may not believe it is necessary to engage in extreme preventive strategies. The third component of this internal inventory is to assess the resources that will be available for infection control activities. The term *resources* in this context is intended to broadly encompass monetary resources, personnel time, and effort.

Keeping in mind this assessment of mindset and resources, the next step in developing an infection control program is to elaborate what the specific goals will be. For example, published goals for a biosecurity program might include protection of hospital personnel and clients from exposure to zoonotic disease agents, creating an environment in which patient care can be optimized by minimizing the risk of nosocomial infection, optimizing education of personnel and clients regarding important infectious disease hazards, and protecting the operational capabilities of the practice. Using a comprehensive, systematic process for evaluation of disease hazards and design of control systems will then allow design of a logical control system that triages efforts to optimize efficiency. One systematic approach that we have used successfully is Hazard Analysis and Critical Control Points

(HACCP) methodology.[12] After identification of the specific hazards (infections) are most likely to occur as well as when and where in the systems these events might occur or be prevented, the next step is to define specific control measures. As mentioned previously, all of these prevention efforts can be briefly summarized as being effective by decreasing the likelihood of exposing patients to infectious agents. In general, this is achieved either by optimizing hygiene in the environment, personnel, or patients or by decreasing direct and indirect contact among patients. To understand which control measures are of greatest importance and where efforts should be targeted, it is critical to consider the life-cycle and methods of transmission for the specific agents of concern. Among the questions that should be asked are the following: Is the agent most likely transmitted through direct contact, or are respiratory aerosols or contaminated surfaces and fomites also important sources of exposure? Is there a subclinical carrier state associated with agent shedding, or is shedding mostly restricted to clinically affected patients? Does the agent persist well in the environment, and can common disinfection procedures readily inactivate organisms?

Each potential infectious disease may be considered individually in this evaluation process, but it is useful to remember that control measures that are effective against one agent are usually effective against others, particularly if they share common routes of transmission or have common risk factors in patients. Design of infection control programs should focus on practical control plans for known problems, but it is important not to ignore the potential for newly recognized and reemerging diseases. Infectious diseases continue to emerge internationally, and many are of relevance to large animal veterinary medicine. The general strategy used in infection control protocols should be sufficiently rigorous to protect against most emerging issues, at least at a basic level. However, infection control programs should also be adequately fluid that they can be modified to address new issues.

Another critical aspect in the practice of infection control is effective targeting of disease prevention efforts. Taken to a hypothetical extreme, the most rigorous infection control methods would prescribe that *every* patient be handled in complete isolation, using barrier precautions verging on those used by “hazmat” personnel. Clearly this is not practical or needed in most situations, and yet in a few rare circumstances this level of precaution can be warranted. In many more situations, some lesser level of precaution is warranted beyond that used in casual encounters with animals in their environments. By their very nature, extra measures used to decrease infection risks inevitably inconvenience caregivers and clients in addition to increasing costs associated with care. In addition, these measures, particularly taken to the extreme, could affect patient care and result in a corresponding *increase* in morbidity. The challenge is to target prevention efforts to just those patients that warrant increased concern and to use the most appropriate, albeit inconvenient, methods for controlling risks to personnel and other patients.

Another side effect of the inconvenience created by infection control efforts is that people by their very nature gravitate to the most convenient methods for daily activities. The more personnel are inconvenienced by infection control efforts, the less likely they are to follow prescribed policies *unless* they understand and believe that procedures are needed and have value. Therefore a critical component of any effective infection control program is maximizing awareness of personnel and educating them about potential hazards and the value of established control measures. Presenting nightmarish worst-case scenarios without other objective information may be initially effective in getting people's attention, but continually using this approach as justification for infection control inevitably fails to truly motivate all or even most personnel. Establishing interactive communication regarding risks and concerns coupled with logical, objective, evidence-based presentations is clearly a better approach for convincing personnel of the need to fully participate in infection control efforts. However, this is also dependant on engaging sufficiently in surveillance and investigation so that useful objective information will be available regarding the significance of specific disease risks in a practice.

46.2.1 Informed Consent and Implications for Infection Control

The principle of informed consent, as it applies to veterinarians caring for animals, implies that owners have the right to be provided with adequate information before treatment so that they can make appropriate decisions for their animals and themselves.[13,14] As professionals with specialized training, veterinarians are expected to have knowledge about the health and care of animals that goes beyond that of someone without this training. One of the components that experts generally agree is part of the informed consent process is the disclosure of potential risks that may be associated with a veterinarian's management of a client's animals, particularly in situations in which there is greater than average risk for a particular adverse consequence.[15] It is reasonable and prudent for veterinarians to routinely disclose the potential for nosocomial infections as part of the informed consent process for all patients. This is especially true for patients with an enhanced risk of acquiring a nosocomial infection (e.g., because of required invasive procedures or because patients are immunocompromised). However, it is also true that if veterinarians know there is an increased risk of nosocomial infections at a facility, there is likely an ethical and legal obligation to disclose before admission how this risk pertains to new patients. In situations in which there is an increased risk of nosocomial infection (if not in all veterinary care situations), it is extremely prudent to document in writing the informed consent process with clients.

1525 1526

46.2.2 Paying for Infection Control Activities

As mentioned previously, procedures used to decrease the risk of nosocomial infections inherently increase labor and material costs related to patient care. If infection control activities are an essential part of delivering veterinary care, then it should reasonably be expected that these costs will be passed on to clients, and it should not be expected that they will be paid for by veterinarians or hospitals. This includes the costs for additional care that is necessary to treat complications associated with nosocomial infections. This assumes that prudent and reasonable precautions have been employed in an effort to manage nosocomial disease risks for patients. In addition, if nosocomial infections are an expected risk related to care of any patient, then veterinarians and hospitals should develop plans for management of financial issues related to these risks. It is also important to differentiate consideration for how charges might be presented to the client from how costs for infection control activities are accounted for. These costs might be passed on to clients by directly accounting for each item, which is most reasonable when there are specific charges that can be attributed to a specific patient (e.g., increased costs related to care of a specific patient in isolation). However, this is less applicable to costs related to care and protection of more than one patient (e.g., costs related to cleaning and disinfection of the environment). In these cases it may make more sense to compensate for costs by aggregating expenses into a general fee category related to infection control (such as a daily biosecurity surcharge) or to include these costs in overhead costs that are covered by general admission or hospitalization fees. In special circumstances, such as when it is necessary to investigate or mitigate against suspected outbreaks of infections, it is useful to have a contingency fund that has been accrued and earmarked to pay for unforeseen expenses such as mass testing, additional labor related to cleaning and disinfection, and so on. Administrators should ensure that the possible need for these monies in case of infection control emergencies is considered and that fee schedules are sufficient to allow development of this type of reserve fund.

46.3 Environmental Hygiene

Much attention is paid to the possible role of the inanimate environment in hospital-associated infections of large animals. Contamination of the inanimate environment by microorganisms is inevitable and entirely expected, and

detection of microorganisms in a hospital environment does not, by itself, indicate anything of clinical relevance. Various factors are likely involved in the potential clinical relevance of contaminants, including the organism, numbers present, likelihood of contact with susceptible hosts, degree of susceptibility of potential hosts, environmental effects (temperature, ultraviolet exposure, humidity), and routine infection control protocols. Many microorganisms grow well on environmental surfaces, provided there is adequate moisture and organic debris, and may survive for very long periods of time. Even with relatively inhospitable conditions, many organisms persist for extended periods. If environmental pathogens are able to contact the appropriate body site of a susceptible individual in adequate numbers, disease could result. Environments where patients are housed or veterinary care is delivered can be expected to have greater numbers of environmental microorganisms than corresponding areas with less animal and human traffic.[16]

The relevance of environmental contamination is often difficult to determine. Even recovery of genetically indistinguishable organisms from the environment and from a patient does not confirm that exposure to an environmental reservoir was the source of infection, as it can be difficult to distinguish cause versus effect. Environmental contamination, however, is of concern for both direct transmission (e.g., oral inoculation from a reservoir of microorganisms in a stall) and indirect transmission (e.g., transmission of an organism from an environmental reservoir to the hands of a care provider and then to an animal). Measures should be used in all veterinary care environments to reduce the environmental pathogen load. This involves cleaning and disinfection of environmental sites.

46.3.1 Cleaning

Cleaning is defined as the removal of all visible debris.[17] It is arguably the most important step in decontamination of animal environments. Even the best disinfectants will be minimally effective when used in the presence of moderate volumes of dirt and organic debris such as feces and bedding material. Dirt and debris hamper disinfection by inactivating many chemicals, acting as a physical barrier between disinfectants and microorganisms, and providing a nutritional source for microorganisms. Not only does cleaning enhance efficacy of the disinfection process by providing optimal conditions for desired biochemical reactions, cleaning can actually remove a majority of microorganisms so that fewer need to be killed by disinfectants. Therefore removal of as much organic debris as possible is required for optimal disinfection. This involves manual labor consisting of removing all bedding and feces and scrubbing all surfaces to remove adherent debris and biofilms. Detergents should be used to loosen organic debris, emulsify fats, and decrease biofilm formation. The disinfectant to be used must be considered when choosing a detergent because there can be interaction between chemicals in detergents and disinfectants.

Because of the effort required to clean and scrub a stall, less labor-intensive methods are often sought. For example, cleaning with high-pressure (>120 psi) power washers is frequently employed in barns and hospitals. 1526
There are theoretic advantages that seemingly justify use of high-pressure washers, especially when they are 1527
designed to dispense high-temperature water and steam. However, whereas power washing is quite helpful in removing organic debris, infectious agents can easily be aerosolized and dispersed over wide areas if pressure washers are used indiscriminately. The true risk related to the use of high-pressure washers is unclear. However, the convenience of using high-pressure systems must obviously be balanced with more intensive manual cleaning methods in order to minimize untoward consequences. Using high-pressure systems on surfaces with large amounts of gross contamination should clearly be avoided.[18] In areas likely to be contaminated with important contagious pathogens (e.g., isolation facilities), it is logical to minimize use or at least use them only as a secondary cleaning process on surfaces that have been previously manually cleaned and disinfected.

46.3.2

Disinfection

Even with proper cleaning and selection of an appropriate disinfectant, disinfection errors can occur. It is critical that disinfectants be used at appropriate concentrations allowing for adequate contact time. It is also important to consider that microbial responses to disinfectant exposures are not uniform. There is tremendous variation in the ability of microorganisms to tolerate cleaning and disinfection. Most enveloped viruses are easy to eliminate, whereas protozoal oocysts, nonenveloped viruses, and bacterial spores may be difficult or impossible to kill.[19]

For disinfection to be effective, a few key factors must be considered: the presence of organic debris, disinfectant concentration, temperature, and contact time. Organic debris inactivates disinfectants to varying degrees, emphasizing the need for careful cleaning. Most disinfectants are available as concentrates and must be diluted before use. Excessively dilute disinfectant solutions may have little or no effect, whereas excessively concentrated solutions can be dangerous to use in addition to being wasteful of resources. Dilution of disinfectants is an important process and must be performed by measurement, not estimation. One solution that makes it easier to ensure that disinfectants are appropriately diluted is to use metered dispensing units that can be either wall mounted or attached to the end of a hose. For some disinfectants, different concentrations may be recommended for different situations. Test strips that can commonly be purchased from restaurant supply companies can also be used to verify appropriate dilution and activity disinfectant solutions. This is especially important when stock solutions are prepared for use over time. Cleaning staff must be informed of the importance of disinfectant dilution and trained in proper methods. Contact time is critical, particularly for certain disinfectants and difficult-to-kill microorganisms. If disinfectants are applied and immediately rinsed away, there is little chance that they can be effective. Most disinfectants require 10 to 30 minutes of contact time. Chemical reactions that produce disinfection are slowed in cold temperatures, which should be considered when determining the amount of contact time that is required. Disinfectants should never be combined because of the potential for inactivation and production of toxic gases.

Disinfection processes can be divided into three categories: high-level, intermediate, and low-level. High-level disinfection involves elimination of all viruses and vegetative bacteria but not all bacterial and fungal spores or protozoal oocysts. High-level disinfection is, in reality, difficult to attain and is uncommonly used. Intermediate disinfection involves eliminating all vegetative bacteria but not necessarily all viruses (especially nonenveloped viruses), spores, or oocysts. Low-level disinfection results in elimination of most but not all potentially pathogenic bacteria. Items requiring disinfection should be classified as to the level of disinfection required, examples of which are shown in Box 46-1.

46.3.2.1

Box 46-1 Examples of Items Requiring Different Levels of Disinfection

46.3.2.1.1

High level

Endotracheal tubes

Tonometer tips

Cystoscope

46.3.2.1.2

Intermediate Level

Dental equipment

Endoscopes

Thermometers used on multiple patients

Vaginal specula

46.3.2.1.3

Low level

Thermometers used on individual patients

Feeding instruments

Muzzles

Nasogastric tubes

Oral specula

Stethoscopes

46.3.3

Disinfectants

It is critical to be aware that all disinfectants do not have the same effectiveness. As with antimicrobial drugs, disinfectants have a spectrum of activity that can be highly variable among disinfectant classes (Table 46-1) Choosing the most appropriate disinfectant can be complex, involving a variety of factors including spectrum of activity, relative efficacy in the presence of organic debris, toxicity to animals and humans, potential damaging effects on certain surfaces, cost, and potential environmental effects. There is no standard disinfectant to be used in all situations in large animal facilities, although oxidizing agents such as accelerated stabilized hydrogen peroxide and peroxymonosulfate are increasing in popularity because of their broad spectrum of activity, acceptable performance in moderate amounts of organic material, relatively rapid action at room temperature, relative safety for personnel, and environmental friendliness. Other options may be appropriate in certain situations. When disinfectants with a narrower spectrum of activity are used as the primary disinfectant, protocols should be in place to use alternate products should certain situations be encountered that require a higher level of activity.

46.3.4 Effect of Surface Material on Cleaning and Disinfection

The material to be cleaned and disinfected can also have a tremendous impact on efficacy. Many surfaces found in large animal clinics and farms are not amenable to thorough cleaning and disinfection. These include unsealed wood surfaces, unsealed block, dirt flooring, and areas that are difficult to clean.

For stalls, solid walls with a sealed surface are optimal for disinfection. This may be difficult to achieve; however, there are certain procedures that can be performed to facilitate disinfection.[18] Cement block walls can be reasonably well sealed with at least two coats of good-quality enamel. Wood walls can be sealed using two or more coats of marine epoxy. Regular maintenance of stalls is required to seal defects that occur from kicks or chewing.

Table 46-1 Disinfectants Commonly Used in Veterinary Medicine*

Disinfectant	Activity in Organic Debris	Spectrum	Comments
Bleach (sodium hypochlorite)	Rapidly inactivated	Broad, including nonenveloped viruses and bacterial spores; no activity against *Cryptosporidium*	Used to disinfect clean environmental surfaces. Sporicidal activity is particularly useful. Efficacy decreases with increasing pH, decreasing temperature, and in the presence of ammonia and nitrogen. Varying concentrations can be used. 1:64 dilution of standard commercial bleach is most commonly used. Higher concentrations, up to 1:10, can be used but should be reserved for infrequent use in special situations. Inactivated by cationic soaps or detergents and sunlight. Chlorine gas can be produced when mixed with other chemicals. Bleaches fabrics and is corrosive to concrete.
Quaternary ammonium	Moderate	Variable; in general, effective against gram-negative bacteria and enveloped viruses, variably effective against gram-positive bacteria, limited activity against enveloped viruses, and no activity against bacterial spores or *Cryptosporidium*	There are differences between different types of quaternary ammonium compounds. Commonly used primary environmental disinfectant, although the spectrum is not necessarily optimal. In general, low toxicity. Inactivated by anionic detergents. Some residual activity after drying. Less effective in cold temperatures and low pH. Stable in storage.
Phenols	Very good	Relatively broad spectrum, with limited activity against nonenveloped viruses and no activity against bacterial spores or *Cryptosporidium*	Main advantage is better activity in organic debris. Can be irritating to skin and mucous membrane surfaces. Reportedly toxic to cats and pigs. Some residual activity after drying. Noncorrosive.

Peroxygen and accelerated hydrogen peroxide	Very good	Broad spectrum, including bacterial spores and nonenveloped viruses; some activity against *Cryptosporidium*	Excellent choice for routine environmental disinfection, footbaths, and environmental fogging. Rapid action makes them a good choice for footbaths. Low toxicity except at high concentrations. Environmentally friendly. Can be corrosive to plain steel, iron, copper, brass, bronze, vinyl, rubber, and concrete. More expensive than most other disinfectant options.
Alcohols	Rapidly inactivated	Moderate No activity against nonenveloped viruses, bacterial spores, and *Cryptosporidium*	Not appropriate for environmental disinfection. Can be used to disinfect certain medical and patient care items, but better options are available. Flammable. Minimally toxic. Fast acting.
Chlorhexidine	Rapidly inactivated	Moderate Limited activity against enveloped viruses No activity against nonenveloped viruses, bacterial spores, and *Cryptosporidium*	Not appropriate for environmental disinfection. Appropriately diluted solutions are suitable for use on tissues or on materials that contact skin or mucous membranes. Minimally toxic. Bactericidal activity on skin is more rapid than many other compounds, including iodophors. Residual effect on skin diminishes regrowth.
Povidone iodine	Rapidly inactivated	Moderate Limited activity against enveloped viruses No activity against nonenveloped viruses, bacterial spores, and *Cryptosporidium*	Not appropriate for environmental disinfection. Appropriately diluted solutions are suitable for use on tissues or on materials that contact skin or mucous membranes. Minimally toxic, but some people can become sensitized to skin contact. Appropriate dilution is important to maximize activity.

* It is critical to handle disinfectants and other chemicals using appropriate safety precautions. Refer to Material Safety Data Sheets (MSDSs) for each product to obtain recommendations regarding appropriate handling and personal protective equipment that is recommended.

The optimal floor surface, in terms of cleaning and disinfection, is a smooth, solid, completely sealed surface. However, surfaces meeting these criteria are not all amenable to animal housing, so a compromise may be required. Finding the right balance of floor cushion, traction, durability, ease of cleaning, and cost is difficult. Regardless, certain key factors should be considered. The floor should be completely sealed so that water (and pathogens) cannot seep underneath, as this creates an obvious environmental reservoir and prevents adequate contact with disinfectants. Damaged stall matting has been cited as the likely environmental reservoir associated with serious outbreaks of nosocomial disease.[10] If obtaining a seamless, water-impervious floor surface is not possible, floor coverings should be completely removable (e.g., rubber mats over sealed concrete floor) and must be removed regularly for disinfection. Remember that dirt, sand, and other organic materials cannot be disinfected and are therefore unsuitable for permanent flooring in hospital stalls or other veterinary care facilities. If sand is required for care of orthopedic patients, plans should be made to completely remove and discard this material between every patient.

46.3.5 Animal Contact Items

After use, all items in a patient's stall should be considered potentially contaminated with pathogens that the animal might be shedding. Therefore for patients suspected or known to have contagious diseases, every item in the stall should be treated as a source of infectious material and must be appropriately decontaminated or discarded. Many stall items may be difficult to disinfect, or it may not be possible to be confident in the ability to fully decontaminate them. If it is cost effective, disposal of these items is ideal. Otherwise, standard principles of cleaning and disinfection apply. It must be recognized that rough, damaged, and permeable surfaces may be very difficult to adequately disinfect. Particular attention should be paid to disinfection of surfaces that patients contact orally, such as feeders and water bowls, and surfaces likely to be contacted by hands of personnel. Appropriate decontamination of automatic water bowls can be problematic. Ideally, the water supply should be turned off, the bowl should be drained and cleaned, and disinfectant should be applied for an appropriate time before the bowl is rinsed and the water is turned back on. Nets used to hold hay have a high likelihood of contamination and are difficult to disinfect without use of gas or plasma sterilization techniques. Therefore their use should be avoided if possible.

Certain items may be at particular risk for contamination. For example, thermometers used on animals with salmonellosis are almost assuredly contaminated, and complete disinfection of digital thermometers is very difficult. It is reasonable to dedicate thermometers to individual patients and discard them when they are no longer required. An alternative is the use of disposable temperature strips, which are sometimes used in human medicine. These have not been specifically validated but are routinely used in some large animal hospitals.[20]

Twitches and muzzles have a high potential for contamination with pathogens such as *Streptococcus equi* and methicillin-resistant *Staphylococcus aureus* (MRSA). Rope used for twitches is extremely difficult to disinfect, apart from removing the rope for autoclaving. Chain twitches are easier to disinfect, but many find them less desirable to use. The ideal twitch material is easy to disinfect and atraumatic and provides good grip on the nose. It is debatable whether the ideal material is available at this time. Twitches should be routinely disinfected to the best of degree possible, considering the material. Consideration should be given to regularly changing or autoclaving rope used for twitches and routinely decontaminating twitches with the understanding that complete disinfection may not be possible. Twitches that are used on animals harboring nasal or upper respiratory tract pathogens should be considered contaminated and material discarded or disinfected.

Few areas show a greater difference in approach to infection control between human and veterinary medicine than the handling of needles after use. In human medicine, recapping of needles is strictly forbidden because of the potential for needlestick injuries and subsequent exposure to life-threatening blood-borne pathogens. In veterinary medicine, recapping of needles is very common, and needle-stick injuries are not perceived to be a significant health threat to veterinary personnel. Currently there are minimal risks to veterinary personnel in almost all situations regarding blood-borne transmission of infectious agents from large animals. However, infectious disease hazards clearly are continuing to emerge, and it is prudent to develop safe practices that minimize the potential for exposure to blood-borne pathogens that might be transmitted from domestic large animals.

46.4 HAND HYGIENE

Rigorous use of hand-hygiene procedures is one of the oldest recognized infection control measures and is perhaps the most important single infection control measure that can be performed. Unfortunately, extremely poor compliance with good use practices in human and veterinary hospitals as well as in the community negate much

of the benefit that can be realized. Centers for Disease Control and Prevention (CDC) guidelines suggest that health care workers in human hospitals should wash hands or use hand-sanitizing products before and after every contact with patients, as well as before eating, and after using the restroom. It is hard to argue that less stringent procedures are warranted in veterinary hospitals.

46.4.1

Box 46-2 Indications for Hand Hygiene in Medical Practice

- When hands are visibly dirty or contaminated with proteinaceous material, blood, or other body fluids
- Before direct contact with patients
- Before donning sterile gloves for invasive procedures (e.g., suturing wounds)
- Before inserting an indwelling urinary catheter, peripheral vascular catheter, or other invasive device that does not require a surgical procedure
- After contact with a patient's intact skin
- After contact with body fluids or excretions, mucous membranes, nonintact skin, and wound dressings
- After contact with an inanimate object in the immediate vicinity of a patient
- After removing gloves
- Before eating and after using a restroom

Adapted from Boyce JM, Pittet D: Guideline for hand hygiene in health-care settings: recommendations of the Healthcare Infection Control Practices Advisory Committee and the HICPAC/SHEA/APIC/IDSA Hand Hygiene Task Force, *Infect Control Hosp Epidemiol* 23(Suppl):S3, 2002.

Numerous indications for hand-hygiene procedures in health care settings have been identified as part of guidelines for human medicine (Box 46-2). As evidenced by this box, hand hygiene is needed frequently in a clinical situation, something that may be problematic in typical settings where veterinary care is provided to large animals. Maintaining optimal hand hygiene can be especially important for ambulatory clinicians and yet can also be particularly difficult to achieve because of logistic difficulties. A variety of options exist for decontaminating hands. The most common practices are hand washing and use of waterless hand-sanitizing solutions. Both are acceptable methods in most situations, and each has individual benefits and drawbacks.

46.4.2

Hand Washing

Washing with antibacterial soap has been the standard method of decontaminating hands of health care workers for over a century. However, the potential benefits of this practice generally are never realized because of failure to use appropriate methods or failure to wash hands at all.[21] Common errors in hand washing include inadequate duration of hand washing, failure to use soap, use of contaminated items to dry hands, and contamination of hands immediately after hand washing (e.g., through contact with contaminated faucets or door handles). An appropriate technique for hand washing is outlined in Box 46-3.

The importance of the type of soap used in hand washing is also often overlooked. Plain soaps, those without antibacterial agents, have minimal direct antibacterial activity. The main benefit of these is assistance with

removal of dirt and organic debris, although efficacy data are conflicting. The use of plain soap can slightly decrease bacterial numbers on hands, but studies in human medicine have failed to demonstrate effective removal of significant pathogens from the hands of hospital personnel.[22] Also, the routine use of plain soap can at times be associated with *increases* in numbers of bacteria carried on hands if use of these products, results in skin damage and irritation through drying.[23] Plain soaps are therefore not an optimal choice for routine use in medical settings, but use is certainly preferable to not washing hands in the absence of suitable alternatives (such as in field settings).

46.4.2.1

Box 46-3 A Recommended Technique for Hand Washing

- Wet hands first with water, then apply an appropriate amount of disinfectant soap (as recommended by the manufacturer).
- Vigorously rub hands together for *at least* 15 seconds, covering all surfaces of the hands and fingers. Make sure to scrub fingertips and clean under fingernails.
- Rinse hands with water and dry thoroughly with a disposable paper towel. Multiple-use towels of any type are not recommended.
- Use towel to turn off the faucet (and open doors when exiting a restroom).

Avoid using hot water, because repeated exposure to hot water may increase the risk of dermatitis. Adapted from Boyce JM, Pittet D: Guideline for hand hygiene in health-care settings: recommendations of the Healthcare Infection Control Practices Advisory Committee and the HICPAC/SHEA/APIC/IDSA Hand Hygiene Task Force

Infect Control Hosp Epidemiol 23(Suppl):S3, 2002.

Most soaps used in hospital settings contain biocides such as triclosan or chlorhexidine. Both of these can produce greater decreases in skin contamination compared with plain soap, and both compounds have antibacterial effects that persist after application,[21] although the duration of activity is shorter against gram-negative organisms (especially *Pseudomonas* species).[21] Iodine and iodophors have been used as skin disinfectants and have a broader antibacterial spectrum. However, both (particularly iodine) can be irritating to skin and are less commonly used for routine hand washing and skin disinfection in medical personnel. In addition, some people become sensitized to skin contact with these products.

Compliance with hand washing protocols is often poor for a variety of reasons. The time required is a major factor, particularly in situations where contact with a large number of patients is likely. Although hand washing requires less than a minute to complete, if it is indicated 100 times in a day, cumulatively this represents a significant amount of time committed to this activity. Lack of convenient access to proper hand-washing facilities is also frequently a problem. If access to sinks with running water, soap, and disposable towels is not convenient (i.e., not adjacent to where animal contacts occur), then it is less likely that hand-washing protocols will be rigorously followed. Regardless of the type of soap used, frequent hand washing can also lead to skin irritation,[21] which compounds compliance problems by making people reluctant to wash their hands and by making hand surfaces more amenable to colonization by bacteria.

Nail care and jewelry can also be significant impediments to achieving optimal levels of hand hygiene.[24] Colonization with higher bacterial numbers, colonization with bacterial pathogens, and outbreaks of infectious

disease have been reported in human hospitals in association with effects related to long fingernails and artificial nails.[25] Studies have shown that these hamper effective hand disinfection, and many health care facilities, particularly intensive care units, prohibit their staff from having long (≥¼ inch) or artificial nails. The role of these factors in risks to patients in veterinary settings is unclear, but some veterinary facilities have developed similar protocols and restrictions.

1530

1531

46.4.3 Waterless Hand Sanitizers

An alternate approach designed to make hand hygiene easier and more accessible involves the use of waterless hand sanitizers. Most waterless hand sanitizers use varying concentrations of alcohol (isopropanol, ethanol, n-propanol, or a combination), whereas a few products contain alcohol plus biocides, or biocides alone. Alcohol products are most commonly available, with concentrations ranging from 60% to 95%. Most products are available as gels, but newer products are dispensed as foams, which may increase acceptability of products. Products with alcohol concentrations >95% are less effective because the presence of water is important for the bactericidal activity. Alcohols have excellent effect against gram-positive and gram-negative bacteria but not bacterial spores or protozoal oocysts.[21] Antiviral effects are variable, with less reliable effects against nonenveloped viruses. Alcohol-based products have been shown to have good effect on reduction of hand contamination of health care workers and have been shown to be more effective than standard hand washing.[26] Frequent contact with alcohol can lead to significant drying of skin, so most commercial products contain emollients, humectants, or similar skin-conditioning agents. Alcohol-impregnated towelettes are also commercially available but contain a small volume of alcohol and are no more effective for hand decontamination than washing with plain soap.[27]

One concern that is sometimes expressed about waterless hand sanitizers is their activity in the presence of organic debris. This is a particular concern in large animal practice, where the likelihood of gross contamination is high and access to hand-washing facilities is sometimes limited. However, a study of the efficacy of hand sanitizers on hand disinfection after performing physical examinations in horses reported that both alcohol and alcohol-chlorhexidine hand sanitizers were more effective for decreasing bacterial contamination than washing hands for 15 seconds with antibacterial soap.[28] This level of disinfection was noted even though the culture fluid collected off the hands was visibly dirty, indicating that there was a reasonable amount of gross contamination. Thus, waterless hand sanitizers are likely to be effective in normal large animal practice situations. When there is readily apparent contamination of the skin, however, debulking of the hands is probably required for optimal effect. It is important to remember that alcohol-containing products are flammable. Although very rare, fires have been associated with exposure to open flame. Common sense, and ensuring that hands are rubbed together until all the alcohol has evaporated, should greatly minimize any risks.

Although most available products contain alcohol alone, some commercial products contain alcohol plus other biocides such as chlorhexidine. Some of these products have sufficient efficacy such that they are widely used for presurgical hand disinfection. The main advantage of using this combination of products is the residual antibacterial effect that the chlorhexidine confers. Some users complain of a “sticky” feel to the skin, which is one of the reasons that this combination is less commonly used for routine situations.

One of the main advantages of waterless hand sanitizers is their portability. It is difficult to make water sources for hand washing portable or always accessible, but these products can be easily placed in ambulatory vehicles, can be carried by individual staff members, and can easily be placed throughout hospitals. Therefore there is a greater likelihood of obtaining compliance by facilitating access. Unfortunately, regardless of the types of products used, compliance with hand hygiene is often a major problem.[29,30] Infection control programs need to

address hand-hygiene compliance through a variety of means to increase use of this critical infection control tool.

46.4.4 Surgical Hand Antisepsis

Scrubbing of the hands and forearms with disinfectant solutions is a standard practice before surgery. Recommended techniques vary somewhat but typically involve a 5-minute scrub with antimicrobial soap. Some studies have reported acceptable hand disinfection with 2- or 3-minute scrubs.[31] Other studies have demonstrated that a two-step approach using a 1- to 2-minute surgical scrub followed by application of an alcohol-based hand sanitizer is as effective as a 5-minute surgical scrub.[32] One concern with repeated surgical scrubbing is the potential for skin irritation and subsequent increases in bacterial contamination. This has led to evaluation of brushless techniques, such as direct application of waterless hand sanitizers. It has been shown that brushless application of a preparation containing 1% chlorhexidine gluconate and 61% ethanol reduced hand bacterial counts more than did brush application of 4% chlorhexidine soap.[33]

There may be some concern about sole use of brushless techniques in situations where there may be moderate debris contamination, as could be encountered in veterinary applications. Various hybrid techniques have been recommended, including performing a hand wash or full surgical scrub at the beginning of the day, followed by application of a waterless hand sanitizer product as the sole hand antiseptic technique for subsequent procedures, or performing a brief hand wash before application of a waterless hand sanitizer. The main advantage of these may be elimination of alcohol-resistant bacterial spores.[34] One factor to consider, however, is that alcohol products may work better on dry hands, so hands should be allowed to thoroughly dry if hands are washed before application of an alcohol hand sanitizer.[34]

46.5 BARRIER PROTOCOLS AND PROTECTIVE ATTIRE

Barrier nursing techniques are an important infection control tool. The basic premise for their use is that placing some type of barrier between caregivers and patients prevents skin or clothing from being contaminated, and the contaminated outer barrier item can be discarded or left in the contaminated environment. Prevention of contamination of people's skin, regular clothing, personal items, and medical instruments can substantially reduce the risk of transmission of pathogens between animals, contamination of the general environment, and zoonotic transmission.

46.5.1 Use of Barrier Precautions

Basic barrier techniques should be used in all veterinary hospitals. Standardized, clean protective outerwear should be worn over hospital-dedicated attire for any patient contact, regardless of the anticipated nature of contact or the assumed infectious disease status of the patient. The need for other barrier items varies with circumstances and is often dictated by the type of disease syndrome being managed (e.g., diarrhea or gastrointestinal disease, respiratory disease, wound infection, fever of unknown origin) as opposed to as opposed to specifically documented infections or diseases (e.g., patients that are culture-positive for contagious pathogens). Other factors that might indicate a need for additional barriers include farm of origin (e.g., farms with endemic *S. equi equi* or rotavirus infections) or a patient that is considered to have an increased risk of infection (e.g., compromised neonates). Gloves, gowns, and overboots are the items most commonly used for additional barrier protection, but masks, caps, and eye protection may also be required at times. In some

facilities, overboots are not used in all areas, but personnel are required to wear footwear that can be readily disinfected, and disinfection of this footwear is required after exiting potentially contaminated areas.

46.5.2 Limitations of Barrier Precautions

The greatest limiting factors associated with use of barrier precautions in infection control are poor compliance and improper use. Written protocols should be developed that document practical use protocols for barrier precautions. These should specifically state when additional barriers are required; it is not possible to achieve consistent results if protocols are ambiguous or suggest too much discretionary interpretation. In addition, it is critical to educate personnel regarding the need for barrier nursing precautions and on proper application. It is also important to regularly monitor compliance with protocols.

46.5.3 Protective Outerwear

Standard protective outerwear for large animal veterinary personnel should include clean coveralls, lab coats, scrubs, or other dedicated clothing (hospital uniforms). Protective outerwear should be worn for every animal contact and should be changed regularly. This includes any time outerwear becomes visibly soiled or otherwise contaminated with body fluids perceived or known to be contaminated with potential pathogens (e.g., feces, blood, nasal exudates, urine, or uterine fluid). In addition, outerwear should be changed frequently (at least daily) because gross contamination does not need to be present for pathogen contamination to have occurred. Hospital personnel should change their hospital outerwear before leaving the building to decrease the risk of transfer of infectious agents from the hospital to the community. In order to facilitate this control measure, it is optimal from an infection control perspective for veterinary practices to provide laundry services or laundry facilities. Clothing that is potentially contaminated with biohazardous material should be handled appropriately so that personnel handling laundry are aware of the hazards and how to reduce risk of exposure.

46.5.4 Gloves

Gloves are an important component of barrier precautions if used properly. The CDC recommends glove use by health care workers to reduce the risk of transmission of infections from patients to personnel, to prevent health care workers' skin flora from being transmitted to patients, and to reduce transient contamination of the skin on the hands of personnel by microorganisms that can be transmitted from one patient to another.[35] The same concepts apply to veterinary medicine. In certain situations glove use has been shown to be an effective means of reducing pathogen transmission in human medicine.[36] However, incorrect use can negate these effects, or even be harmful. Common errors with glove use include failure to wear gloves when needed, not changing gloves after contact with infectious items, touching items (e.g., pagers, cell phones, pens, medical supplies) while wearing contaminated gloves, contamination of hands or clothing while removing gloves, and failure to wash hands after glove removal.[37] Although gloves are used to prevent contamination of hands, the potential for inadvertent contamination through microbreaks in the glove surface or contamination during glove removal necessitates use of hand washing or application of hand-sanitizing solutions in conjunction with their use.

There are no widely accepted standards in veterinary medicine for when gloves must be used, apart from the use of sterile gloves during surgical procedures. Examination gloves that are clean but not sterile are often used when handling wounds and infected body sites and during contact with animals known or suspected to be shedding contagious pathogens. Despite relatively widespread use of examination gloves in a variety of

circumstances in veterinary medicine, it is quite unusual for practices to have formal protocols regarding how and when they should be used.

46.5.5 Gowns

Whereas protective gowns have traditionally been used only during surgery, their use as a barrier garment when contacting high-risk patients is increasing in both human and veterinary medicine. The CDC has produced guidelines for human medicine stating that “gowns should be worn by personnel during the care of patients infected with epidemiologically important microorganisms to reduce the opportunity for transmission of pathogens from patients or items in their environment to other patients or environments.”[35] In general, gowns should be worn whenever direct or indirect with patients or their environment may result in contamination of caregivers' clothing or skin that facilitates transmission of pathogens.

The ideal barrier gown would cover all areas of the body that might become contaminated, would prevent penetration of liquids, would be of adequate strength to resist tearing and puncture under normal activities, would be comfortable to wear for long periods, would be available in appropriate sizes for all personnel, would be easy to put on and remove without contamination of regular attire, would be nonabrasive to skin, would be unlikely to startle patients, and would be of acceptable cost. Unfortunately, a product with all of these characteristics does not currently exist, and facilities must prioritize the relative importance of different gown properties. This is often difficult because neither the overall effectiveness of gowning nor the effectiveness of different gowns in veterinary situations has been adequately evaluated. The problem most likely to be encountered with barrier gowns in veterinary practice is poor resistance to liquids, especially under direct contact or pressure. In large animal practice, there is a greater likelihood of contact with relatively large volumes of fluids (e.g., with diarrheic animals) or direct contact with patient surfaces that would have moist secretions or excretions (e.g., animals with nasal discharge or large infected wounds). The types of anticipated activities may also affect the required size of gown. Gowns that do not completely cover the legs and feet may be useful in some circumstances but ineffective in situations with prolonged direct contact such as with assisted neonatal nursing.

In human medicine, there are conflicting data regarding the efficacy of gowning for prevention of hospital-associated infections.[38,39] Gowns may be more effective for reducing infection of personnel. It is possible that the most significant advantage in some situations is not the protective effect of gowns or other protective outerwear, but rather the raised awareness of the potentially infectious nature of the patient, which may in turn encourage concurrent application of other important infection control practices.

1532

1533

46.5.6 Eye Protection

The use of protective eyewear, including goggles and face shields, is common in human medicine during procedures that generate aerosols or airborne droplets of blood, body fluids, and secretions.[40] Use of these items is mandated in some instances by health and safety regulations.[41] Despite the current low prevalence of blood-borne zoonotic pathogens in large animal species, it would be prudent to consider the use of some type of eye protection whenever generation of aerosols from liquids or secretions that might contain contagious pathogens is likely to occur. Situations in which eye protection should be seriously considered include examination of animals with suspected viral encephalitides.

46.5.7 Respiratory Protection

Masks and respirators are often used to reduce the risk of exposure to infectious agents by respiratory and oral routes, to reduce the risk of contamination of patient sites with organisms from personnel, and in some situations to prevent contamination of hands with nasal or oral microflora. Standard surgical masks may be effective against the spread of large particle droplets that are transmitted by close contact and travel only short distances (up to 3 feet) from infected patients.[42] However, the overall effectiveness of standard masks has come under debate, and some authors have questioned the overall effectiveness of surgical masks in hospital situations.[43]

Airborne transmission of zoonotic pathogens is commonly thought to be of minimal concern in most veterinary settings, and mask use is uncommon in veterinary hospitals apart from use during surgical procedures. The actual reduction in zoonotic disease risk that might be associated with the use of surgical masks during routine patient contact is unclear. However, increased awareness of risks of specific zoonotic disease risks, and infections in immunocompromised personnel and others with special disease risks, has prompted reconsideration of recommendations regarding personal protective equipment in some circumstances. For example, although airborne transmission is not considered an important route of exposure for MRSA, hospital personnel primarily become colonized in the nasal passages, and hand-to-nose contact is frequent. Therefore mask use prevents direct contact of hand and nose, thereby decreasing hand contamination or decreasing the risk of inoculation of the nose after contamination of the hands during animal contact. Masks capable of filtering nonoily particulate aerosols with 95% capability (N95 masks) are recommended in human medicine for dealing with airborne contagions such as the severe acute respiratory syndrome (SARS) coronavirus. Although there is currently little indication that these masks are routinely required in large animal practice, it may be reasonable for facilities to at least have a plan in place to implement N95 masks if required. A critical aspect of the use of N95 masks is fit-testing and training in their use, as improperly fitted or used masks may confer little or no benefit over surgical masks.

46.6 ANIMAL MOVEMENT AND HOUSING

Housing and movement can have a profound effect on the likelihood of exposure of patients to pathogens. Ideal facilities have no contact between inpatients and outpatients, allow for grouping and segregation of animals with different risks for contagious diseases, prevent direct contact between adjacent animals, reduce the potential for indirect exposures through contact with contaminated environments, and have adequate space so that there is time to properly disinfect all housing and handling environments between uses with different animals.

One major problem frequently encountered in large animal facilities, particularly older facilities, is that construction and design factors often hinder infection control activities. Infection control issues were not always given high priority during the design of many older facilities, so various problems are often encountered. These include patient traffic flow problems, requisite mixing of inpatients and outpatients, inability to segregate different cohorts in the population, heavy traffic around important areas (e.g., surgery, isolation), inadequate stall numbers, inadequate isolation facilities, poor ventilation, improper drainage, use of materials that are difficult to clean and disinfect, design issues that hinder adequate cleaning and disinfection, and so on. A variety of challenges is encountered when an optimal facility is designed. Many measures used to enhance infection control inherently are inconvenient, and designs that optimize infection control often have a significant impact on building costs and efficiency of use of the facility. It can be difficult to reconcile ease of operation with the level of infectious disease risk that is desired.

46.6.1 Outpatient Areas

In general, outpatients tend to have a lower contagious disease risk, in terms of both likelihood of shedding infectious agents and their susceptibility to infectious disease. However, “lower” risk does not mean “no” risk, and it is important to design holding areas that minimize contact with other animals while clinicians obtain histories and conduct initial examinations to more clearly categorize patients relative to their contagious disease risk. Ideally, outpatients should have little or no contact with inpatient animals and minimal contact with areas visited by inpatients. However, this is often not entirely possible. For example, it is often impractical to build completely separate areas for diagnostic imaging of inpatients and outpatients. However, the general principle of separation of inpatients from outpatients should be adhered to as much as possible.

Holding stalls in admission and outpatient examination areas may need to house a large number of animals every day. Therefore it is important that a sufficient number of stalls is available to allow appropriate cleaning between use, that there are established mechanisms to allow admitting clinicians to identify high-risk cases, and that this information is promptly conveyed to relevant personnel so extra precautions can be taken with that patient and the environment with which it has been in contact. Environmental precautions may range from routine cleaning and disinfection to restricting use pending high-level cleaning and disinfection, stall cultures, or patient cultures.

46.6.2 Inpatient Areas

Inpatients pose greater challenges than outpatients because they often have significant risk factors for infectious disease acquisition such as comorbidity, dietary changes, antimicrobial treatment, disruption of natural defense mechanisms, surgery, and placement of invasive devices. Compromised inpatients, particularly certain patient groups (e.g., those with gastrointestinal disease) may be more likely to shed infectious agents such as *Salmonella enterica*. Thus, infection control protocols should emphasize the need to reduce the risk of transmission of infectious agents from inpatients to other hospitalized animals and hospital personnel, and to minimize risks related to contamination of the hospital environment. A variety of methods can be used to manage this risk; these need to be balanced with levels of risk aversion and available resources to support infection control efforts.

1533
1534

One method of reducing the risk of disease transmission among individuals and groups (e.g., between animals in different wards or those assigned to different services) is to assign animals to different cohorts and then create physical and procedural separation among the different groups. It is important to group animals based on known or suspected infectious disease status or infectious disease susceptibility, as well as to group and separate animals with different disease syndromes (e.g., respiratory disease or gastrointestinal disease). It is also logical to group and segregate animals that are managed by different clinical services in order to decrease the probability of transmitting infectious agents through indirect contact. As an example, because of the documented risk associated with *Salmonella* shedding among cattle from intensively managed populations, several large hospitals have found that it is very important to house and manage cattle separately from other large animal patients (especially horses). In general, managing inpatients as smaller cohorts helps contain transmission risk, thereby decreasing the likelihood of a widespread outbreak in the entire patient population. Creating smaller cohorts of patients with different risks for contagious disease also facilitates the use of varying levels of infection control precautions for different groups.

The design of some facilities does not allow for the separation of different cohorts in different buildings or wards. When physical separation of inpatient groups (excluding isolation cases) is impossible or impractical,

animals with different disease risks can still be managed differently in a common ward system. One approach is to designate areas within large wards for different cohorts. Another is to identify animals in different risk categories, applying different levels of infection control precautions, but to allow interspersing of animals from different risk categories in the same area. Physical separation within a ward can be enhanced by use of chain or rope barricades to identify and minimize access to patients with elevated contagious disease risk status. A key for successful infection control using this type of system is the absolute need for prominent identification of different groups, having defined protocols for each group, and maintaining effective communication about disease status of these patients. One system that has been employed is the use of color labels to indicate infection control status. For example, colored adhesive dots can be placed on stalls or stall cards of all patients; red dots might indicate animals with a known highly contagious disease, yellow dots might indicate that animals are suspected of having an infectious disease or may have increased risk of acquiring infectious disease, and green dots might indicate that animals are considered to have an average or low risk of carrying or acquiring contagious disease agents. This type of system is easy to apply and easy to understand. In addition, more prominent signs can be used to more clearly indicate to all personnel certain concerns (e.g., *Salmonella*, MRSA, rabies suspect). One consideration with these more specific labels, however, is whether visitors could obtain confidential and sometimes prejudicial information from visible notices.

46.6.3 Isolation of Highest-Risk Patients

The most rigorous control of contagious disease hazards requires that transmission potential be absolutely minimized for patients suspected or known to be infected with highly contagious pathogens or pathogens associated with highly consequential diseases. In general this means that these patients should have no direct or indirect contact with other animals or areas used in routine care of patients via personnel, fomites, aerosols, or other materials. It also means that human access to these patients and their care environment should be tightly controlled. In general, in order to achieve this level of isolation, these patients will require housing in a separate, specially designed unit.

Most isolation protocols in large animal medicine focus on a limited number of pathogens. Protocols for large animal facilities tend to focus heavily or solely on *S. enterica*. Whether these protocols are adequate or excessive for control of other pathogens is debatable, and a broader scope is likely required in many facilities. That said, protocols that reduce the risk of transmission of one agent generally reduce the transmission potential of other agents, particularly if there are similarities regarding transmission routes or risk factors for exposure and infection.

Large animal isolation protocols need to take into consideration a variety of issues, including indicators for isolation, cleaning and disinfection protocols, protocols regarding personnel movement and barrier precautions, protocols for patient contact and movement, manure disposal, and supply stocking. Defining methods for identifying animals that need to be isolated and establishing specific criteria for handling these animals is critical, and these methods must be properly communicated to all individuals associated with patient or facility care. Developing protocols for rapid identification of patients that represent a contagious disease hazard is critical to the success of any biosecurity program. The best isolation units are not effective if unoccupied. Specific disease and syndromic criteria for isolation should be developed to facilitate prompt isolation of appropriate individuals. Isolated animals should be physically separate from the rest of the hospital population at all times if at all possible. This means that isolation units should be designed so that animals will rarely if ever have to leave the unit except for those that need an emergency procedure such as surgery. Stocks, examination areas, and scales should be available. Ideally, there should be minimal contact of personnel with isolated animals and their stall environment. The ability to monitor patients in isolation using viewing windows

or by remote electronic means (e.g., web cameras, closed circuit video) facilitates the ability to deliver excellent patient care while minimizing risks associated with direct contact.

These units must be strictly managed with specific predetermined protocols in order to reliably manage the risk of transmission. Isolation protocols should be comprehensive and clearly documented in writing. Proper training of all staff, particularly lay staff who may have no background in infectious diseases and infection control, is critical. Standardized protocols for management of isolation units in human health care settings have been published by the CDC.[42] However, similarly standardized guidelines have not been established for veterinary medicine, and protocols used at veterinary facilities are highly variable as they are tailored to specific operations and different facility and logistic resources. It is logical for veterinary facilities to consider guidelines that have been developed at other veterinary facilities and in human health care settings when developing their own isolation protocols.

In some situations, housing of potentially infectious animals in an isolation unit is not possible because of patient care issues or limitations in isolation space. As a result, consideration needs to be given to management of higher-risk patients within the general hospital environment. This can be done in a few different ways, including grouping of general risk groups and application of intermediate isolation techniques to patients that are considered at higher risk for being infectious but that are not deemed candidates for housing in an isolation unit. In-hospital isolation protocols allow for an increased level of protection but are not a replacement for a proper isolation unit and should not be used solely for clinician convenience. Protocols should be developed regarding the handling of animals, the stall, and the area around the stall. Animals that are isolated in the hospital should not leave stalls unless they are being moved for required procedures. If movement is necessary, feet should be cleaned and disinfected using appropriately diluted chlorhexidine solutions. The potential for environmental contamination can be reduced by having a person follow the animal with a bucket to collect any feces that may be passed during transit. Traffic areas should be promptly cleaned and disinfected. Protective barrier clothing such as full waterproof coveralls or full-length waterproof gown, gloves, and dedicated footwear or boot covers should be worn for any contact with the patient or its environment. The area around the stall entrance should be considered potentially contaminated and disinfected routinely (at least three or four times per day). Disinfectant footbaths or footmats used at stall doors can reduce bacterial contamination of footwear.[44,45] Attention should be paid to the pattern of water drainage from the stall and in the area. If water runs from the stall to the breezeway or runs down the breezeway past the stall, then housing of potentially or known infectious animals in the stall may be inappropriate. Animals should not be allowed contact with neighboring animals. Barriers may be required if solid walls are not present on all sides. Specific protocols should be developed for cleaning in-hospital isolation stalls. These stalls should be cleaned last, personnel cleaning stalls must wear protective gear, and items used to clean the stall must be disinfected immediately after use.

1534

1535

Isolation guidelines for human medicine target the prevention of five different types of transmission: contact transmission, droplet transmission, airborne transmission, common vehicle transmission, and vector-borne transmission.[42]

- Contact transmission is typically the most important mode of transmission and involves transmission of infectious agents to patients by caregivers or directly between patients. In large animal medicine, this could include situations such as transfer of MRSA from a colonized person to an animal under care, transmission of *S. equi* between horses by personnel, or direct transmission of viral respiratory pathogens between horses in adjacent stalls that can have nose-to-nose contact.

- Droplet transmission involves transmission of infectious agents in relatively large fluid droplets generated by coughing, snorting, or vocalizing. These large droplets do not remain suspended in the air for long periods, nor are they transmitted long distances; therefore special air handling is not required. An example of this is transmission of bacterial agents from a coughing horse to another horse stabled in relative proximity. An extrapolation to veterinary context might also include transmission of surface contaminants during environmental cleaning processes with water under high pressure.
- Airborne transmission involves agents that can be transmitted effectively in small particles (5 μm or smaller) that can remain suspended in air and travel greater distances. Special air handling is required to control this route of transmission. Equine influenza can be spread through a barn via the airborne route over extended distances.
- Common vehicle transmission involves infection caused by contact with contaminated items such as feed bins, muzzles, twitches, thermometers, and other medical equipment.
- Vector-borne transmission involves vectors such as mosquitoes, flies, and rodents. This may be of particular concern in some areas with reportable vector-borne diseases such as equine infectious anemia.

46.7 SURVEILLANCE

All comprehensive infection control programs should have a surveillance component, as the information collected serves as sensory input to guide ongoing efforts so that they are focused and efficient. Without surveillance information, infection control programs will be guided more by emotions and opinions than by data and evidence. Infection control programs will have much greater acceptance and utility if in the long term decisions are based on objective information about infection and disease occurrence at a specific hospital. Useful surveillance goals for infection control programs include developing a system to allow prompt identification of contagious disease threats, evaluating the effectiveness of infection control practices, measuring personnel compliance with infection control procedures, providing a basis for logical infection control decisions, and stimulating efficient and economical use of resources.

46.7.1 Surveillance Options and Strategies

Theoretically, an optimal surveillance system would allow real-time detection of every occurrence of nosocomial infection. However, pursuing this goal would be unrealistic for reasons of practicality and would be an inefficient use of resources. Although all nosocomial infections are important relative to patient well-being, some are more important than others. This is because the impact on patient health is much more significant for some diseases, and also because highly contagious diseases are more likely to affect a larger number of patients. Focusing surveillance on these high-impact nosocomial infections is logical, as a greater proportion of these occurrences are also likely to be preventable in comparison with more sporadic problems. Furthermore, experiences with infection control in human health care settings have shown that it is possible to be more efficient with infection control and just as effective if special high-risk or high-cost problems are targeted.

Determining which specific nosocomial infections were likely preventable is a difficult and potentially contentious task. Rather than focus on individual infections, infection control efforts in human hospitals have benefited by focusing on comparing rates of infection and estimating the proportion that might be preventable by referencing some accepted standard. During the past 30 years, human hospitals have made great efforts to characterize rates of nosocomial infection that can be expected even under the best of circumstances. By

estimating rates for these “nonpreventable” infections, it has then been possible to identify hospitals with higher than average rates for nosocomial infections. Because of the tremendous differences among hospitals and among patient populations, it has become standard to focus on more restricted, high-risk patient groups for which there is better comparability (e.g., neonatal or cardiac intensive care patients). It is also far more feasible to perform surveillance for nosocomial surveillance in these high-risk patient subgroups than it is in the larger general population, which has a much lower risk of nosocomial infection. Performing surveillance with standardized case definitions over time allows identification of specific risk factors, which could then be used to prospectively refine management of patients (e.g., a high-risk patient could be identified and be subjected to more aggressive control measures as a preventive strategy). Unfortunately, there is very limited information available regarding rates of nosocomial disease that can be found at individual hospitals, let alone estimation in multiple hospitals, which would be required in order to obtain interhospital comparisons that would be useful in identifying latent problems at specific facilities. Although making standardized comparisons among hospitals would require tremendous cooperative effort, individual facilities could make significant progress in identifying important changes in nosocomial infection rates if efforts were made to benchmark their nosocomial infection rates over time.

1535

1536

When designing a formal surveillance effort to aid infection control programs, it is important to tailor efforts to a specific facility or practice. There is a wide variety of design possibilities for hospital surveillance systems, and the specific focus and methods should be carefully matched to the needs and resources of each establishment. Diseases that are the highest priority for surveillance must be specified, along with standardized case definitions that will be used to identify these cases. Efforts may target nosocomial disease related to specific procedures or organ system involvement, or just as commonly they may target specific infectious agents of interest. For example, systems might be established to look for surgical or intravenous catheter site infections, methods may target surveillance for respiratory tract infections, or efforts may specifically target detection of *Salmonella* or MRSA infections. It must also be determined whether clinical disease will be the outcome of interest or whether it is important to look for animals with subclinical infections. This will generally vary by disease and likely will be determined by the natural history or pathophysiology of the disease (e.g., Does shedding occur in the absence of clinical signs? Is there a chronic carrier state? What are the risk factors related to the likelihood of shedding?). Furthermore, if clinical disease is the outcome of interest, it is important to consider whether the case definition will include some type of confirmation of the cause or whether diagnoses will be more based on clinical signs and syndromic in nature (e.g., surgical site infections could be defined based on recovery of a bacterial agent in the presence of clinical disease, or they could be defined solely on the presence of a predetermined combination of clinical signs such as erythema and drainage). As discussed previously, another consideration is whether surveillance will target specific subgroups of the population or whether it will include all patients. The major benefit of targeted surveillance is that it decreases the cost and effort of data collection, but the tradeoff is the inability to detect potential problems in the patients that are not being monitored. However, increasing awareness about infection control methods for common or more important diseases generally has the effect of increasing awareness and compliance with control measures that relate to other potential nosocomial problems. It also must be determined whether surveillance will be active (i.e., patients with nosocomial problems will be actively sought out) or whether passive surveillance (i.e., reporting is voluntary) is acceptable and appropriate. In general, active surveillance will be used only in targeted subpopulations and only to look for more common and more important diseases, and syndromic surveillance should be more heavily relied on when the targeted population is larger or as a supplement to culture or etiologically based surveillance efforts.

Another important consideration is how data will be gathered for this effort. Significant personnel compliance is needed for active culture-based surveillance of large numbers of patients. Similarly, any type of chart review system for benchmarking expected rates of nosocomial disease requires a significant time commitment.

Surveillance efforts are greatly aided by the ability to use computer-based search mechanisms, and it is strongly recommended that any practice use electronic medical record systems to maximize the ability to perform surveillance. For example, something as simple as being able to monitor the number of febrile or leukopenic patients on a daily basis could be extremely powerful as an aid to infection control efforts. Even financial databases can be useful in surveillance efforts. For example, financial databases may be very useful for surveillance for benchmarking antimicrobial prescriptions or specific procedures, such as intravenous catheterization or surgeries.

Monitoring for bacterial contamination of the hospital environment has been a useful adjunct to patient monitoring in comprehensive biosecurity programs at veterinary hospitals.[20,46,47] In addition, in some situations, such as when attempting to control ongoing outbreaks, there is no substitute for culturing the hospital environment to detect important environmental reservoirs.[10,48] Use of electrostatic household wipes has been extremely useful for sampling to detect *S. enterica* in routine surveillance as well as in the face of outbreaks.

As an alternative to culturing environmental samples for one specific agent, it may be useful to enumerate total numbers of bacteria recovered from hospital surfaces using either swabs or contact plates (e.g., RODAC).[16,47] Contact plates are simple to use, require minimal investment of labor, and when used on regular basis can provide valuable information regarding cleanliness of hospital surfaces. Such data can be used as feedback for the cleaning personnel, for monitoring of quality of cleaning, or for pinpointing problem areas. It is important to remember that bacteria can be recovered from most surfaces, even in the cleanest of hospitals. Therefore, in order to be most meaningful, if quantitative environmental cultures are to be performed they should be repeated on a regular basis in order to establish meaningful baseline values for comparison.

The use of rapid and sensitive diagnostic tests is particularly important for the management of highly contagious diseases. Polymerase chain reaction (PCR) and antigen detection tests, which can be much more rapid than traditional culture systems for bacteria and viruses, have become more widely used for both patient and environmental surveillance efforts. However, these tests cannot fully replace culture-based assays, because analysis of microbes is essential to fully understand the epidemiologic implications of each recovery. For example, if on a single day three patients were found to be shedding *Salmonella* using PCR assay, it would not be possible to know whether these were unrelated events. In contrast, if shedding were detected using culture and the *Salmonella* isolates were then shown to be from different serogroups, this would make it unlikely that shedding was related to nosocomial exposures from a single source. In some situations it may be logical to use both rapid and culture-based assays to maximize both speed and ability to perform epidemiologic investigations. Availability of qualified laboratories, rapidity of testing, and costs will all have to be considered and balanced in these considerations.

46.7.2 Monitoring Personnel Compliance

Success of an infection control program is absolutely dependent on corporate participation that arises from a well-developed sense of responsibility among individuals. Actively engaging all personnel in biosecurity programs becomes increasingly difficult as organizations become larger and more complex. Unfortunately, the most cautious actions of a majority of personnel can be for naught if even one individual neglects to take appropriate precautions under just the right (wrong) circumstances. Although it is very important for administrators to engage in surveillance to detect systematic noncompliance with policies, it is just as important to empower all personnel and expect them to participate in monitoring for individual acts of noncompliance. Remembering that most noncompliance arises from a natural tendency for people to revert to the most convenient practices (which are not necessarily the most “safe” from the biosecurity perspective), it is

important to couple surveillance efforts with education so that all personnel fully understand why they are being inconvenienced. In addition, providing useful feedback and communication about issues that arise in the hospital will help to reinforce the need for compliance. For example, monitoring and reporting of bacterial shedding or environmental contamination detected as a part of surveillance programs can help to keep hospital personnel aware of the potential hazards of reduced biosecurity efforts.

46.7.3 Measurements Related to Health and Disease

Although outcomes for individual animals may be the most important bottom line for many clinicians, it is important to remember that infection control by its very nature often has a larger population-based perspective. Therefore, although diagnostic tests results have great relevance for an individual animal, a positive test result may not have great value for the entire population unless it is interpreted contextually. As such, it is critical to remember that some type of denominator information is needed in addition to numerators to provide relevance over time or for different subpopulations (e.g., numbers of all infections, numbers of animals tested). Some examples of relevant denominators include patient admission totals for a given period, patient-days of hospitalization, procedure events such as surgeries or catheter placements, and culture totals.

46.7.4 Developing a Comprehensive Surveillance Strategy

As mentioned, it is unrealistic to expect to detect all occurrences of nosocomial infection or all animals shedding agents of interest through any hospital surveillance system. Rather, veterinarians should work toward developing strategic surveillance programs that will allow reliable estimation of rates for important events if they occur with any significant frequency, as well as rapid detection of “unexpected” important events. It is likely that a mix of strategies described earlier will be used for the various agents and disease problems. For example, if *S. enterica* shedding occurs at some low-level yet regular frequency in a hospital (e.g., 3% of all hospitalized equine patients) and it is considered an important potential hazard for other patients, it is reasonable for an active surveillance program to be developed that allows detection of clinical and subclinical shedding of *Salmonella* as a patient management tool and also allows detection of important trends over time so that nosocomial outbreaks could be rapidly identified and stopped. In contrast, *Clostridium difficile* and *Clostridium perfringens* may not have been detected with any regularity in patients at a particular hospital or may be more difficult to actively monitor because of available testing methodologies, yet they may still be considered important because of their significance as pathogens and their potential for contagious spread. For these pathogens, it may be more reasonable to use a reliable passive surveillance strategy to call attention to patients when clinical signs or culture results indicate that these agents may be present. In addition, maintaining some level of surveillance for compliance with infection control procedures and policies is necessary to ensure that a biosecurity program is functioning properly.

46.8 EDUCATION AND AWARENESS

Education of all personnel regarding infectious disease hazards to themselves, patients, and veterinary practices is essential to the long-term success of any infection control program. Successful programs are critically dependant on all personnel knowing and following procedures and policies used for control of contagious disease transmission in a practice. Although this type of information can be acquired over time through personal experience, this is an inefficient and unreliable method for disseminating critical information.

46.8.1 Written Protocols

The first step to ensuring that necessary information is disseminated to all personnel is to document policies and protocols in writing. This effort is valuable for all veterinary practices but is especially critical in larger and more complex veterinary hospitals. This relatively simple step has many benefits. First, documenting procedures requires a thorough review, which by itself is beneficial. Second, documenting policies and protocols in writing imbues the infection control program with a sense of purpose and commitment. Third, documenting procedures helps to ensure consistency in application by all personnel as well as over time. As discussed, all infection control procedures are inherently inconvenient, and the natural tendency is for personnel to drift toward more convenient ways performing activities, which may not provide an adequate degree of protection against nosocomial infections. Fourth, documented policies demonstrate a degree of due diligence, which is useful from a legal liability standpoint relative to the occurrence of nosocomial or zoonotic infections.

Once these protocols have been documented, it is important to require their use as a reference and to make a specific effort to educate personnel about the policies and procedures. A written document serves no purpose if it is not used. Veterinarians and other personnel are busy people, and the immediacy of caring for patients and clients can easily overwhelm seemingly mundane tasks such as studying written protocols. A valuable aid in this process is to have some type of training program. This does not necessarily mean formal presentations; it is valuable to organize a meeting of all personnel for the sole purpose of discussing infection control issues. Although this seems logical, biosecurity training is not a universal occurrence even in teaching hospitals. In a survey of teaching hospitals from American Veterinary Medical Association (AVMA)–accredited institutions, only 15 of 37 responding institutions reported that they required that personnel (students, technical staff, veterinarians) participate in some type of formal training program regarding infection control and biosecurity, and only seven of these institutions provided more than a single training exposure.[49]

46.8.2 Training Programs

It is also important to consider the differences in training and experience among personnel. By their nature, infection control programs are dependant on adherence to important protocols by all personnel regardless of their position description. Nonveterinarians are invaluable members of most veterinary practice teams, and even personnel who might never touch patients but instead are employed as receptionists or for the single specific task of cleaning are absolutely critical for the success of infection control programs. Veterinarians sometimes underappreciate how their specialized training has provided them a broad appreciation for basic principles of contagious disease transmission and control. Without the experiences of a veterinary education, many personnel do not have the same basic understanding of contagious diseases. Simply telling people to follow certain rules leads to inevitable compliance problems. Although it is important for people to know what is expected of them, it is just as critical for them to know why these procedures are important. Without a thorough understanding of why inconvenient infection control practices are needed, they will inevitably be discarded over time as seemingly illogical. To help ensure uniformity of exposure among all personnel, some hospitals have developed training documents and require that new employees pass a written evaluation before they are permitted to begin work.

1537 1538

Another important aspect of education and awareness is to instill a need to lead by example and to empower all personnel to hold anyone else in the practice accountable for his or her actions. The hierarchy in authority that is needed in the delivery of patient care (veterinarians at the top of the hierarchy, personnel without formal training at the bottom) can interfere with optimal infection control. A common non sequitur related to infection

control is that those with the most training can be the persons least likely to adhere to important policies. This is true both in human and veterinary medicine, as has been repeatedly shown relative to hand hygiene.[21] Physicians and residents have been shown in numerous studies conducted in a variety of settings to be significantly less likely than nurses to adhere to appropriate hand-hygiene protocols. Observations in the veterinary setting suggest that the same trends are true for hand hygiene, as well as for appropriate use of barrier nursing precautions. All people pick up cues for behavioral expectations from their surroundings. If personnel who clearly understand the importance of preventive measures such as hand washing (physicians and veterinarians) fail to routinely follow best infection control practices, there is little hope that trainees and laypersons will routinely trouble themselves to habitually use an important albeit inconvenient practice. Furthermore, it seems that the more respected the position a person holds in a practice, the more likely it is that individual acts of noncompliance will influence the actions of others. Students in teaching hospitals can watch classmates correctly follow infection control policies throughout the day and yet can be more influenced to be noncompliant by observing the single time that a senior clinician ignores a practice guideline.

One way to improve compliance and counter these influences is to use disseminated enforcement by actively encouraging all personnel to call attention to noncompliance. Once it has been determined which procedures are required for a particular situation and this has been documented, there is no reason that nontechnical staff should be any less capable than a veterinarian in determining whether a procedure has been correctly followed. It is important that this community enforcement be empowered by all in a spirit of friendly camaraderie and team building. Some hospitals have noted significant improvements in compliance using this method of enforcement and have even used competitions between “teams” with the incentive of agreeing that the loser must pay a reward to the other team (e.g., pizza lunch).

46.8.3 Zoonosis Awareness

One of the most important objectives for an infection control program is to protect personnel and clients from illness associated with zoonotic infections. This is another area in which veterinarians sometimes forget that not all personnel have an understanding of hazards or of how to take appropriate actions to protect themselves. Without this knowledge, personnel may take inappropriate risks or may overreact to perceived hazards in what is actually a low-risk situation. In addition to holding briefings or question-and-answer sessions, it is wise to provide a good resource text, written summaries, or URL addresses of reliable Internet resources so that personnel have tools available to help them research answers to their questions. Table 46-2 provides a brief summary of some zoonotic pathogens that might be transmitted from domestic large animals through occupational activities of veterinary personnel.

46.8.4 Personnel with Increased Risk of Infection

An important area for which there is not much published literature relates to risks for zoonotic infections in personnel who have an increased susceptibility to infectious diseases or those in whom the consequences of clinical infection may be particularly severe. Obviously there is an overall increase in risk of infection for immunocompromised personnel, but there is very little specific information about which disease risks might be of greatest importance to this population. In addition, it is essentially impossible to predict which agents are of little risk to people with a healthy immune system but may be of much greater risk to immunocompromised personnel. Individuals being treated orally with antimicrobial drugs are generally considered to have an increased risk for infections with enteropathogens, so it is prudent for personnel being treated with antimicrobial drugs to be especially attentive to protocols related to personal protection. Pregnant women have a special risk for infections that can result in fetal infections or abortion and should therefore employ practical

precautions that reduce the likelihood of infection. In general, paying strict attention to good hand-hygiene protocols, routine use of gloves to reduce the likelihood of contact exposures, regular use of protective outer garments or hospital dedicated-attire, and avoiding eating and drinking around animals or in their environments should help to reduce the likelihood of exposure to potential zoonotic pathogens.

46.9 INTERVENTION AND INVESTIGATION OF NOSOCOMIAL OUTBREAKS

An outbreak is defined as an increased occurrence of infections above the expected baseline (endemic) level. Outbreaks are an ever-present risk in all health care facilities, veterinary or otherwise, and outbreaks will occur despite rigorous infection control protocols. The general principles of outbreak management are to contain the outbreak and reduce the overall impact on individual animals and the facility. It is critical to note that despite the stigma that is often attached to outbreaks, an outbreak of disease does not necessarily indicate poor management or malpractice. By their very nature, most veterinary hospitals will always have higher risks for the occurrence of outbreaks of infectious disease. However, making no attempt to identify nosocomial infections, neglecting signs of a developing outbreak, or responding inappropriately to the spread of nosocomial infections could all be construed as poor management or even malpractice. There are numerous reasons why plans for a logical, aggressive, organized, and cooperative response should be developed. Consultation with internal and external experts in epidemiology, infectious diseases, microbiology, and infection control can be useful. It is unlikely that the person involved in coordinating the outbreak response will be an expert in all areas. Consulting others does not indicate a lack of ability on the part of the response team; rather it indicates a logical approach to a typically complex problem. It makes sense to consult with those who through interactions at multiple facilities have gained experience that cannot usually be obtained while concentrating on primary responsibilities as a clinician at a single institution. Ideally, these individuals are consulted early in the outbreak, and it may be prudent to develop contingency plans and contact consultants in anticipation of potential problems. The use of external consultants can be particularly useful because they can examine a situation and facility without the same degree of inherent bias that develops through experience and habit of regular daily practice in a facility.

1538 1545

Table 46-2 Zoonotic Diseases of Domestic Large Animal Species That Are Transmissible through Occupational Exposures to Veterinary Personnel*

Agent or Disease	Susceptible Animal Species	Clinical Signs in Humans	Methods of Transmission to Humans	Personal Protection for Veterinary Personnel
***Bacillus anthracis* (anthrax)** Gram-positive, spore-forming, anaerobic bacterium	All species	There are three clinical forms of anthrax in humans: cutaneous, pulmonary, and gastrointestinal. Cutaneous infections manifest as skin papules and vesicles with associated cellulitis that evolve into a characteristic black eschar (scab). Pulmonary anthrax initially resembles upper respiratory infection and can evolve into severe respiratory compromise and death. The gastrointestinal form results in gastroenteritis with vomiting and dysentery.	Cutaneous transmission occurs through direct contact; respiratory transmission occurs through inhalation of bacteria or spores; gastrointestinal transmission results from eating undercooked contaminated meat.	Enhanced barrier precautions, including eye protection and a minimum of N95 respiratory protection, should be used when handling affected animals or working in their environments. Blood and secretions from anthrax suspects should not be allowed to contact skin. Necropsy should not be performed on animals that have died from anthrax.
Bordetella bronchiseptica Gram-negative bacterium	Pigs, dogs, cats, rabbits, horses	Disease is rare in humans and occurs almost exclusively in immunocompromised individuals, resulting in pneumonia and upper respiratory tract infections.	Respiratory infection through contact and droplet routes.	Immunocompromised individuals should avoid contact with mucous membranes and nasal discharges of susceptible animal species. Barrier precautions and adherence to good hand-hygiene protocols will reduce the risk of exposure.

Brucella melitensis, Brucella abortus, Brucella suis, and ***Brucella canis*** **(brucellosis)** Gram-negative bacterium	Cattle, sheep, goats, camelids, pigs, horses, dogs, and other species	Flulike illness, gastrointestinal signs occur frequently in adults but less often in children; irritability, insomnia, mental depression, and emotional instability sometimes develop. Recurrent fevers are the hallmark of chronic infections, in addition to fatigue, arthritis, and cardiac and other complications.	Contact, droplet, or aerosol exposure to infected fetuses, placenta and placental fluids, or infected tissues, contact with contaminated fomites. Ingestion of unpasteurized milk or milk products.	Avoid contact with fluid or tissues from abortions. Use of barrier precautions including gloves, protective eyewear, and a minimum of N95 respiratory protection are recommended when performing obstetric procedures or performing necropsies on high-risk animals.
Burkholderia mallei **(Glanders and Farcy)** Gram-negative bacterium	Horses and other equid species	Flulike symptoms, photophobia, lacrimation, diarrhea, septicemia, pneumonia, ulcerative and suppurative cellulitis, lymphadenopathy, splenic and hepatic abscesses.	Direct contact or droplet exposures to skin or mucous membranes; prolonged contact with infected animals is generally required for infection.	Enhanced barrier precautions, gloves, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols are warranted when working with infected animals.
Campylobacter jejuni and ***Campylobacter coli*** Spirochete bacterium	Cattle, sheep, goats, camelids, pigs, poultry, dogs, cats, other species	Disease varies from mild gastrointestinal distress that resolves within 24 hr to fulminating or relapsing colitis. Signs may include watery diarrhea, fever, nausea, vomiting, abdominal pain, headache, and muscle pain. Feces may contain frank blood. The acute symptoms usually diminish in 2-3 days and resolve in 7-10 days. Complications are rare but include Guillain-Barré syndrome, a disorder of the nervous system.	Fecal-oral transmission after contact with infected animals or their environments is a suspected but not well documented risk factor. Ingestion of contaminated water and food including undercooked poultry or meat, raw milk.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Avoid eating or drinking near animals or their environments.

Clostridium difficile Gram-positive, spore-forming, anaerobic bacterium	Pigs, horses, cattle, dogs, cats, other species	Colitis leading to fever, abdominal cramps, diarrhea or dysentery, dehydration, and electrolyte imbalances. Rarely, severe colitis can lead to life-threatening complications such as megacolon, peritonitis, and colonic perforation.	Oral-fecal exposure through contact or droplet exposure to infected animals or their environments.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments; personnel should use respiratory protection when cleaning practices may produce droplet exposure. Avoid eating or drinking near animals or their environments.
Clostridium perfringens Gram-positive, spore-forming, anaerobic bacterium	All species	Wound infections can result in gas gangrene with accompanying fever, swelling, and erythema of affected area; systemic signs as disease progresses. Oral exposure is associated with abdominal cramps, diarrhea, and in rare cases necrotic enteritis and septicemia.	Wound contamination through contact or droplet exposure, ingestion of food contaminated with large numbers of bacteria, potentially oral-fecal exposure through contact or droplet exposure to infected animals or their environments.	Routine use of protective outer garments or dedicated attire when working with animals or their environments. Strict adherence to good hand-hygiene protocols and appropriate cleaning and management of wounds.

***Coxiella burnetii* (Q fever)** Gram-negative, spore-forming, intracellular bacterium	Primarily sheep, goats, cattle but also camelids, horses, dogs, cats, other species	Symptoms of Q fever include fever, chills, headache, fatigue, and chest pains. Pneumonia and hepatitis can occur in serious cases. In pregnant women infections can cause premature delivery, abortion, and infection of the placenta. In people with preexisting heart valve disease, endocarditis may occur.	Contact, droplet, or aerosol exposure to urine, feces, milk, and especially fetuses and placental tissues from infected animals. Respiratory exposure to contaminated dust, occasionally ingestion of unpasteurized milk or milk products.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Caution is warranted when handling tissues or fluids of infected animals or aborted fetuses. Consider use of eye protection when performing obstetric procedures on high risk-animals. Enhanced barrier precautions, gloves, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols are warranted when working with infected animals.
Cryptosporidium parvum (“**Crypto**”) Apicomplexan protozoal parasite	Ruminants, pigs, horses, poultry, dogs, cats, other species	Gastrointestinal disease, including signs of abdominal pain, nausea, anorexia, and profuse watery diarrheas. Severe infections can require hospitalization for fluid therapy and treatment of electrolyte imbalances. The disease is usually self-limiting but may be chronic and debilitating in immunocompromised individuals.	Oral-fecal transmission primarily through contact with infected animals or their environments but also through droplet exposures during cleaning.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments; personnel should use respiratory protection when cleaning practices may produce droplet exposure. Avoid eating or drinking near animals or their environments.
Dermatophilus congolensis Gram-negative, actinomycete bacterium	Cattle, sheep, goats, camelids, horses, rarely pigs, dogs, and cats, other species	Pustular desquamative dermatitis.	Direct contact with lesions on affected animals.	Use gloves when handling affected animals; strict adherence to good hand-hygiene protocols.

***Erysipelothrix rhusiopathiae* (erysipelas in pigs, erysipeloid in humans)** Gram-negative, facultative anaerobic bacterium	Pigs, other species	Characteristic cellulitis with raised red lesions and edema, intense pruritus. Skin infections can progress to involve other cutaneous sites and also rarely to systemic infections with flulike illness, septicemia, and arthritis.	Primarily via direct contact with infected animals, contamination of skin wounds. There are rare reports of transmission through ingestion of undercooked pork.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Gloves should be used when working with clinically affected animals. Avoid eating or drinking near animals or their environments.
Enterohemorrhagic*Escherichia coli*(e.g., *E. coli* serotypes O157:H7, O111, O26) Gram-negative bacterium	Cattle	Fever, enteritis, diarrhea or dysentery. In children under 5 and the elderly, infections can cause hemolytic uremic syndrome (hemolysis and kidney failure).	Oral-fecal transmission via contact or droplet exposure through exposure to cattle or their environments or through ingestion of contaminated water and food.	Strict adherence to good hand-hygiene protocols, routine use of protective outer garments or dedicated attire when working with animals or their environments. Avoid eating or drinking near animals or their environments.
***Francisella tularensis* (tularemia)** Gram-negative bacterium	Sheep, rabbits, cats, other species	Flulike illness, rashes, nausea, splenomegaly, papular or ulcerative lesions at site of cutaneous exposure, lymphadenopathy and ulcerative lymphadenitis, pleuropneumonia from inhalation or hematogenous spread; ingestion is associated with enteritis, stupor, and delirium.	Contact, droplet, or aerosol exposure to tissues or secretions of infected animals, ingestion of tissues from infected animals.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments is warranted when handling tissues or fluids of infected animals or aborted fetuses. Gloves, eye protection, and a minimum of N95 respiratory protection should be used when performing obstetric procedures on high-risk animals.

Foot-and-mouth disease virus Nonenveloped, single-stranded RNA virus	Cattle, sheep, goats, camelids, pigs, other species	Infection in humans is very rare; headache, fever, vesicular lesions on the hands or feet or in the mouth.	Contact, droplet, or aerosol exposure to infected animals.	When working with infected animals, enhanced barrier precautions, gloves, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols.
Giardia lamblia Flagellated protozoan parasite	Ruminants, pigs, poultry, dogs, cats, other species	Gastrointestinal disease, including signs of diarrhea, intestinal gas, stomach cramps, and nausea. A significant proportion of patients develop lactose intolerance while infected. The illness usually lasts 1 to 2 weeks, but chronic infections can last months to years.	Oral-fecal transmission through contact with infected animals or their environments or through ingestion of contaminated water or food.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Avoid eating or drinking near animals or their environments.
Hendra virus Enveloped, single-stranded RNA virus	Horses, other species	Fever, lethargy, respiratory distress, neurologic signs including headache and disorientation.	Occupational contact with infected horses or their tissues.	Classified as a Biosafety Level 4 agent; contact with infected animals or their tissues should be avoided unless personnel are specifically trained to work with this agent.
Influenza virus (swine flu, avian flu) Enveloped, single-stranded RNA virus	Pigs, aquatic fowl Influenza viruses are generally host restricted.	Cross-species infection with influenza strains is extremely unusual under normal circumstances but has been rarely documented with swine and avian influenza viruses, resulting in fever, malaise, upper respiratory illness, pneumonia.	Close contact with infected pigs leading to respiratory exposure through contact, droplet, and aerosol routes.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. When working with infected animals, use enhanced barrier precautions, gloves, eye protection, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols.

Leptospira species ("**Lepto**") Spirochete bacterium	All mammals appear to be susceptible to at least one species of *Leptospira*.	Severity of illness varies greatly; signs include flulike illness with fever, chills, headache, and severe myalgia. Aseptic meningitis can occur, and 5%–10% of cases may be associated with multiple organ failure.	Skin or mucous membrane contact with urine or less commonly with blood and tissues of infected animals; ingestion in contaminated water or food.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. A minimum of N95 respiratory protection may be appropriate if droplet exposure to urine is likely. Avoid eating or drinking near animals or their environments.
Listeria monocytogenes Gram-positive bacterium	All species	Contact can result in papular lesions on hands and arms. Most commonly flulike illness and gastroenteritis. Less commonly infections can result in a mononucleosis-like syndrome (glandular listeriosis) or in fetal infection, abortion, stillbirth, neonatal septicemia, or meningoencephalitis. Meningoencephalitis is also noted in elderly and immunocompromised.	Immunosuppression greatly increases the risk of infection. Direct contact of skin or mucous membranes with infectious material, feces, or contaminated soil. Respiratory exposure to secretions from infected animals via droplet or aerosol routes. Oral-fecal exposures through contact, droplet or aerosols or ingestion of contaminated foods.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments, especially among immunocompromised people. Avoid eating or drinking near animals or their environments. Enhanced barrier precautions, gloves, eye protection, a minimum of N95 respiratory protection, and strict adherence to good hand-hygiene protocols are warranted when performing obstetric procedures on high-risk animals or when handling aborted fetuses, or tissues and fluids of infected animals.

***Mycobacterium tuberculosis, Mycobacterium bovis, Mycobacterium avium avium* (tuberculosis)** Acid-fast bacterium	All species	Signs depend on the organ system involvement. General signs of infections include anorexia, weight loss, fatigue, fever, chills. Signs of pulmonary infection include coughing and hemoptysis. Skin lesions are characterized by ulcers, papular lesions, and suppurative lesions. Signs of other organ involvement relate to the specific system.	Inhalation and oral exposure through respiratory droplet and aerosol transmission from infected animals, oral or cutaneous exposure through contact with infected tissues or contaminated surfaces, ingestion of raw or unpasteurized milk and milk products.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. A minimum of N95 respiratory protection may be appropriate if working with infected animals with clinical pulmonary disease or if performing necropsy.
Nipah virus Enveloped, single-stranded RNA virus	Pigs, other species	Fever, neurologic signs including drowsiness, headache, disorientation, and confusion, shortness of breath and coughing.	Occupational contact with infected pigs.	Classified as a Biosafety Level 4 agent; contact with infected animals or their tissues should be avoided unless personnel are specifically trained to work with this agent.
Parapox viruses (Orf virus, bovine papular stomatitis virus [BPSV]) Enveloped, double-stranded DNA viruses	Sheep and goats (Orf virus), cattle (BPSV)	Papular lesions at areas of contact (usually hands or arms). Lesions can be 1 cm in diameter, and surrounding tissues often become swollen and painful.	Contact with lesions on animals, scabs, or contaminated objects.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Gloves should be worn when examining mouths of animals suspected of being infected.

Rabies virus Enveloped, single-stranded RNA virus	All mammals	Encephalitis with accompanying behavioral and physical signs.	Bite injuries from infected carnivores, contact with infected animals, and contact with bats or their habitats are the most common methods of human exposure. Contact, droplet, and aerosol exposures to saliva and respiratory secretions of infected livestock are also thought to be possible methods of infection but are not well documented.	Complete isolation of animals suspected of infection, minimizing contact with personnel. When necessary to examine or manage suspect animals, use enhanced barrier precautions, gloves, a minimum of N95 respiratory protection, eye protection, and strict adherence to good hand-hygiene protocols. Personnel that may be exposed to rabies should be vaccinated in accordance with Centers for Disease Control and Prevention (CDC) recommendations.[50]

Rift Valley fever virus Enveloped, single-stranded RNA virus	Cattle, sheep, goats, camelids, other species	Flu-like illness, photophobia, neck stiffness, and vomiting, which may progress in severe cases to one of three characteristic syndromes: eye disease, meningoencephalitis, or hemorrhagic fever. Retinal lesions are the prominent sign associated with eye disease.	Contact with blood, other body fluids, or tissues of infected animals. Accidental inoculation through sharps injuries or by inhalation of droplet or aerosols. People may also become infected by mosquitoes or possibly from ingestion of raw milk.	Extreme caution should be taken when working with animals during epidemics. An inactivated vaccine has been used experimentally to protect veterinary and laboratory personnel at high risk of exposure. Enhanced barrier precautions, gloves, eye protection, and a minimum of N95 respiratory protection are strongly recommended when working with high-risk animals or their tissues. Universal precautions should be taken when obtaining and processing specimens from patients. Samples should be handled only in laboratories by trained staff and processed in suitably equipped laboratories. Control of the mosquito vectors and use of personal protection is important.
Rhodococcus equi Gram-positive facultative intracellular bacterium	Horses; also found in feces of sheep and cattle	A problem with growing recognition, infections in immunocompromised people commonly lead to life-threatening chronic, progressive, granulomatous pneumonia. In contrast, infections are very rare in immunocompetent people and are typically less severe.	Regular contact with horses is a documented risk factor for infection, presumably through oral-fecal exposure via direct contact or droplets, although there is often no documented direct exposure to horses.	Immunocompromised people working with horses should adhere to good hand-hygiene protocols and routinely use protective outer garments or dedicated attire when working with animals or their environments. Avoid eating or drinking near animals or their environments.

Ringworm (*Microsporum* and *Trichophyton* species) Fungi	Cattle, horses, dogs, cats	Characteristic circular, well-circumscribed, red lesions that are pruritic. In immunocompetent people, infection is limited to the keratinized layers of the skin and hairs. However, in immunocompromised people, infections may extend to deep tissues or become systemic.	Direct contact with lesions on affected animals or with objects that have contacted affected areas.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Gloves should be worn whenever working with animals known to have dermatophytosis.
Salmonella enterica Gram-negative bacterium	All species	Flulike illness, gastroenteric disease, diarrhea or dysentery, septicemia.	Oral-fecal transmission through contact with infected animals, their environments, or contaminated items or through ingestion of contaminated water or food.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with animals or their environments. Enhanced barrier nursing precautions are needed when working with clinically affected animals. Avoid eating or drinking near animals or their environments.

***Staphylococcus aureus* (methicillin resistant *s. aureas* or MRSA)** Gram-positive bacterium	Horses, pigs, dogs, cats, other species	*Staphylococcus aureus* commonly colonizes the anterior nares and other sites without causing clinical signs. Infections most commonly involve skin and soft tissues, either as a primary infection or by infecting cuts or other skin injuries, including sites of intravenous injection or catheterization. Infections of the respiratory tract and urinary tract are also noted. The risk of infection may be increased in immunocompromised people. Skin infections most commonly result in swollen, painful, erythematous lesions that can often be purulent.	Direct contact with colonized or affected animals, droplet or aerosol exposure to discharge from infected sites.	Strict adherence to good hand-hygiene protocols and routine use of protective outer garments or dedicated attire when working with horses or pigs. Enhanced barrier nursing precautions and gloves should be required when working with animals known to be colonized or infected. Cuts and abrasions should be kept bandaged and disinfected regularly.
Vesicular stomatitis virus Enveloped, single-stranded RNA virus	Cattle, sheep, goats, camelids, pigs, horses, other species	Infections in humans are very rare but typically result in flulike symptoms. Less commonly, oral vesicles and cervical lymphadenopathy can be noted.	Mucosol exposure via direct, droplet, or aerosol exposures with clinically infected animals.	Enhanced barrier nursing precautions and gloves can be used when working with animals known to be colonized or infected. Eye protection and N95 respiratory protection may also be warranted when examining or treating lesions.

* This is not a complete list of all zoonotic diseases; less common diseases and those with vector-borne or solely foodborne routes of transmission are not included.

One of the most important factors in outbreak intervention is early recognition of potential problems. Ideally, infection control programs should be designed to allow early identification of related clusters of infection or disease either through laboratory testing, clinical disease reporting, or syndromic surveillance. When an infectious animal is exposed to a susceptible population, transmission may occur. First generation transmission—that is, transmission from the index case (directly or indirectly) to other animals—can be difficult to detect, particularly in situations when the index case is infectious before developing clinical disease. The most important control aspect related to the first generation of cases is prompt identification so that an outbreak can be recognized early enough to implement measures to reduce the risk of further transmission to a second generation of cases. Often outbreaks

are not identified or addressed until multiple generations of transmission have occurred, thereby increasing the overall morbidity and mortality and complicating the response.

General principles of outbreak response include identification of the infectious agent, identification of infectious animals, identification of animals that have likely been exposed, determination of the mode of transmission, and prevention of further transmission by means such as isolation, implementation of barrier precautions, active surveillance, environmental surveillance, increased environmental disinfection, restriction of animal and personnel movement, and under extreme conditions minimization of new exposures through restriction of admission of new patients.

Although useful, initial intervention measures do not require definitive identification of the causative agent. In the absence of a confirmed cause (e.g., diarrhea cluster of unknown cause), outbreak intervention can still be performed using general infection control practices combined with knowledge of appropriate response to the most likely causes. General principles such as isolation of infected or affected animals and their direct contacts, use of barrier precautions, close attention to personal hygiene, restriction of animal and human movement, regular examination of animals, and careful attention to cleaning and disinfection are important measures that are useful for most types of infectious disease outbreaks. Indeed, these measures alone will often constitute the full response after a causative agent is identified.

Identification of animals likely to be shedding the agent responsible for the outbreak is critical. Definitive confirmation is not required, and a syndromic response is often better. For example, in the midst of a *Salmonella* outbreak it is wise to consider all animals with diarrhea, depression, or fever as likely to be infected and shedding bacteria even if culture results have been negative. This will result in some misclassification, but erring on the side of being overly sensitive in identifying infectious animals is the more appropriate response when trying to halt the spread of disease. The main problem with this type of response is imposing excessive strain on available resources (e.g., isolation stalls, personnel time) because of excessive misclassification.

Identification of potentially exposed animals is also critical. Depending on the pathophysiology of disease, these animals may or may not require segregation or isolation. For some pathogens, clinical disease precedes development of the infectious state, so exposed animals can be monitored and isolated if required. For example, horses exposed to *S. equi* develop fever before shedding the organism,[51] so close monitoring of body temperature of exposed animals and prompt isolation of animals developing fever may be sufficient to prevent propagation of an outbreak. For many pathogens, screening of all potentially exposed animals can be useful. In particular, the use of rapid screening techniques that can provide a turnaround time of a few hours (e.g., antigen detection test for equine influenza, *S. equi* PCR) can be very useful. However, testing strategies should also include some use of culture so that whole organisms will be available to aid epidemiologic investigations. Widespread screening of hospitalized animals will often be required to determine the extent of the outbreak and facilitate removal of infectious animals from the population. Therefore, if screening is imposed as a response to suspected spread of nosocomial infections, it is essential that it not be an elective procedure. It is prudent for facilities to have previously considered how costs for diagnostic testing will be distributed in the event of suspected nosocomial infections. Surveillance for shedding of specific contagious agents at the time of admission can facilitate prevention of outbreaks as well as intervention responses. In situations where recently exposed animals do not necessarily develop consistent overt clinical signs or where rapid diagnostic testing is not available, it may be necessary to segregate all potentially exposed animals, either in an isolation unit or in the main hospital.

Determination of the likely mode(s) of transmission is also required for initiation of an effective response. This is usually relatively clear based on the identity of the known or suspected pathogen. However, in general, all agents of concern for nosocomial infection will spread through contact and common vehicle transmission, and therefore

controlling all methods of contact exposure to patients will be critical in response to suspected outbreaks. Although droplet transmission might be most important for respiratory agents, practicalities of cleaning hospital environments for large animals usually necessitate use of large volumes of water, which can also create hazards related to droplet transmission. Therefore the potential for droplet transmission should also be tightly controlled in response to suspected outbreaks. Generally, only highly contagious viral respiratory agents pose a hazard through airborne transmission. However, in situations in which routes of transmission are not clear, it is prudent to assume the worst and manage the outbreak as if the pathogen were highly transmissible by multiple routes until proven otherwise.

Prevention of further transmission is obviously one of the most important goals of outbreak response. A variety of factors need to be considered to achieve this. In addition to identification of infectious animals, measures need to be established to prevent direct and indirect contact of these animals with other animals and the general hospital environment. Isolation and the use of barrier precautions can achieve this. The response to implemented infection control measures should be closely monitored to determine their adequacy, with an understanding that there is an inherent lag time from implementation of measures to control of the outbreak that is proportional to the incubation period for infectious diseases.

1545

1546

At times, partial or complete closure of the facility may be useful or necessary. Restricting new admissions decreases the number of newly susceptible individuals that might promote propagation of an outbreak. Furthermore, if new infections appear to be occurring despite implementation of best control efforts, it is important to consider whether it is prudent or ethical to continue admitting new patients. It is also critical to consider the tremendous burden that can be created by the need to deal with infection control measures and the possible effects on patient care. During outbreaks, stall space, particularly isolation space, may become limited, and decreasing the number of admissions facilitates depopulation of the facility for proper cleaning and disinfection. Clinical personnel are often overworked during outbreaks because of the number of ill animals, and excessive workload can contribute to breaches in protocols. There may be reluctance among some people to restrict hospital admissions because of potential negative impacts related to public relations and finances, but early, short-term closure of a facility to stem a small but developing outbreak is much better than a subsequent longer closure in response a larger outbreak with more affected animals. A key component of facility closure is proper communication to staff and the public, emphasizing the proactive approach that is being taken to protect patients and clients and to prevent a major problem from developing. Regardless of whether it is deemed necessary to restrict admission of new patients, as described previously, whenever outbreaks of nosocomial infections are suspected, it is critical to consider whether standard informed consent procedures suitably convey the risks associated with hospitalization to clients.

If environmental contamination is suspected of being widespread, complete depopulation of a ward or even the entire hospital may be necessary to allow for thorough cleaning and disinfection. The availability of multiple wards can facilitate this process, as individual problem wards can be closed and disinfected while the hospital remains functioning. Assuming sensitive culture or other antigen detection methods are available, postdisinfection environmental screening may be indicated for certain pathogens (e.g., *S. enterica*) before a facility is reopened.

Although vaccination is often perceived as being a cornerstone of infection control, the indications and limitations of vaccination must be considered. No vaccine will confer 100% protection, and vaccination should never be used as a replacement for good infection control practices. A more appropriate perspective is that vaccination is principally useful when more useful infection control methods have failed.

Requiring vaccination before hospital admission is an area that has received limited commentary in large animal practices. Although vaccination requirements are difficult to enforce in animals admitted for emergency procedures, it may be reasonable for facilities to consider encouraging or requiring vaccination against relevant

pathogens before admission for elective procedures. For example, requiring vaccination before admission for influenza in horses or bovine viral diarrhea virus in pregnant cattle or alpacas could decrease the risk of infection and transmission in hospitals. Problems that might be encountered with such an approach include the lack of relevant efficacy data for many vaccines, potential concerns regarding adverse effects with some vaccines, difficulty ensuring compliance, and competitive issues if all competing practices do not have the same standards.

Vaccination may be a useful intervention measure during some outbreaks, but efficacy in these situations has not been evaluated. It is important to remember that there are three possible outcomes associated with any intervention: it may help, it may have no effect, or it can be harmful. For vaccination during an outbreak to be helpful in control efforts, the vaccine must be given to susceptible animals before exposure, must initiate a protective response before natural exposure, and must not be harmful when administered to animals that are incubating disease. These criteria are often difficult or impossible to meet in the midst of an outbreak. The greatest potential use for vaccination during an outbreak is likely with the use of intranasal influenza vaccination, as this type of vaccine can provide a rapid and effective immune response and is not contraindicated in exposed animals.

46.10 INFECTION CONTROL ISSUES RELATED TO SPECIFIC PATHOGENS

Although all contagious diseases have the potential to be important hazards for the health of individual patients, there is more empiric evidence regarding the importance of some diseases. Furthermore, although safeguarding the health of veterinary personnel must be a priority for all veterinary practices, some zoonotic diseases have been shown to be of greater concern. Information is listed in the following sections regarding control of diseases of particular importance as nosocomial and zoonotic disease hazards.

46.10.1 Salmonella

S. enterica is the agent most commonly reported in association with nosocomial disease outbreaks and closure of large animal hospitals. In a recent survey of teaching hospitals from AVMA-accredited institutions, 31 of 38 responding institutions (82%) reported documenting outbreaks of nosocomial disease during the previous 5 years and 65% of institutions reported *S. enterica* as being associated with an outbreak (20 of 37).[49] Additionally, most of these institutions (17/20) had to restrict admissions to reduce patient risk or mitigate contamination, and 11 of these institutions closed at least part of their facilities completely. All species are susceptible to infection, but hospitalized cattle from intensively managed populations generally have the highest prevalence of shedding and camelids the lowest. The likelihood of shedding in patients while hospitalized is greatly influenced by the prevalence of infection in animals at home premises. A notable number of patients shed *Salmonella* without evidence of associated illness, but patients are significantly more likely to shed if they are systemically ill. This is especially true if animals show signs of gastrointestinal illness. Numbers of organisms shed per gram of feces are generally much greater in clinically affected animals. Animals known to be infected with *Salmonella* should be managed in isolation with strict barrier precautions and hand-hygiene protocols. Shedding tends to be more commonly detected in the summer and fall and may also be generally more common in warmer climates. Although nosocomial outbreaks are usually detected in association with the spread of clinical disease, subclinical infections can be more common than clinical infections during outbreaks. Zoonotic infections in veterinary personnel have been commonly detected in association with nosocomial outbreaks. There is apparent variability among strains with regard to virulence, infectivity, and ability to persist in the environment, and this strain variability may be a very important determining factor regarding nosocomial outbreaks of infection. Environmental contamination near infected patients is the rule rather than the exception, and active surveillance has shown that contamination can become disseminated to quite distant areas of the hospital from only a single infected patient. In one study 12% of 452 environmental samples collected over 10

weeks in a nonepidemic period using electrostatic household wipes were positive for *Salmonella*.[46] Experience has shown that environmental contamination is even greater during outbreaks. In nonepidemic situations there tends to be great variability in phenotypic markers (serogroup, serotype, and antimicrobial susceptibility) among isolates recovered from patients over time, which often makes it possible to differentiate isolates in epidemiologic investigations. In other situations, especially when certain strains are circulating actively in the region of a hospital, use of genetic analysis may be necessary in order to differentiate strains of *Salmonella* for purposes of epidemiologic investigations. Culture methods used in diagnostic laboratories are highly variable, which can significantly affect assay sensitivity. Veterinarians should seek out laboratories that are known to have optimized culture methods for use in diagnostic situations. PCR assays for *Salmonella* are available commercially at a number of laboratories. However, because of the importance of phenotypic and genotypic comparisons of isolates that are conducted as part of epidemiological investigations, PCR assays are not recommended for regular use in surveillance programs without parallel analysis using culture. Active surveillance programs are commonly used in large hospitals as a management tool to detect clinical and subclinical infections in large animal patients. In addition, environmental surveillance is sometimes used as an adjunct to detect environmental contamination. All common disinfectants are effective against *Salmonella* organisms under optimal conditions. However, its common association with fecal material, other organic matter, and dirt necessitates careful adherence to good cleaning (physical disruption of surface matter using detergents) and disinfection procedures in order to minimize the likelihood of environmental persistence. Mitigation in response to nosocomial outbreaks requires thorough decontamination of all environmental surfaces, which may be possible only after closure to new admissions, although disinfectant misting may be a useful alternative in some situations.[52]

46.10.2 Clostridium difficile

Although less commonly implicated with diarrheic disease than *S. enterica, C. difficile* is a potentially important nosocomial pathogen in horses. *C. difficile* should be considered as a differential diagnosis in horses with diarrhea and duodenitis-proximal jejunitis. Standard infection control methods used for salmonellosis should be adequate to control transmission of *C. difficile,* with the exception of disinfection. Because *C. difficile* is a spore-forming bacterium, disinfection can be difficult. Clostridial spores are highly resistant to environmental degradation, and most disinfectants that kill *Salmonella* are ineffective against bacterial spores, with the exception of bleach (hypochlorite solutions). Accelerated stabilized peroxide and peroxygen disinfectants may also be effective, although less information is currently available. An additional, albeit mostly unsubstantiated concern is the potential for zoonotic transmission of *C. difficile* from horses or cattle to humans. The strains of *C. difficile* isolated from animals are often indistinguishable from those that cause disease in people. Therefore, animals infected with *C. difficile* should be considered as potential sources of zoonotic infections in humans.

46.10.3 Cryptosporidium parvum

Animals of all ages in a variety of host species have been shown to shed *C. parvum* oocysts, but the shedding prevalence is much greater in young animals, and the primary infection control hazard involves shedding by diarrheic neonates, especially calves. This is because of the extraordinary numbers of oocysts shed by affected young animals, the small infectious dose, and the hardiness of organisms. Affected calves can shed more than 10^7 oocysts per gram of feces during peak shedding, whereas humans and other animals can be clinically infected with fewer than 100 oocysts, although there does appear to be some difference among individuals and also among strains. To further complicate control, oocysts are profoundly resistant to all disinfectants that can

be regularly used in hospitals. Research has shown there are different lineages of *C. parvum* that relate to host range; genotype 1 appears to infect only humans, whereas genotype 2 (sometimes called *bovine genotype*) infects a wide variety of other species, including domestic large animals and humans. Cryptosporidiosis is an important zoonotic disease hazard in veterinary personnel, and there are a number of documented outbreaks involving animal caretakers. *Cryptosporidium* is considered to be a relatively common nonviral cause of self-limiting diarrhea in immunocompetent persons, particularly children. Clinical disease can be severe and even life-threatening in immunocompromised persons. Diarrheic neonates can be easily and inexpensively screened using direct microscopic examination of fecal smears prepared with acid-fast stains. Regardless, it is very prudent to house diarrheic neonates in isolation and handle with strict barrier precautions and hand-hygiene protocols. Personnel cleaning these housing areas should avoid using high-pressure water, to minimize the risk of aerosol and droplet exposure. This is complicated by the resistance of coccidian parasites to disinfectants, which necessitates the reliance on vigorous scrubbing with soap and rinsing with copious amounts of water in decontamination efforts. The likelihood of inadvertent oral exposure while cleaning can be reduced by using face shields or N95 disposable masks along with gloves.

46.10.4 Equine Rotavirus

Although outbreaks of rotavirus are not uncommon on breeding farms, outbreaks in veterinary clinics are rare. Equine rotavirus is of most concern in facilities with a large neonatal caseload. Rotavirus may be shed in the feces of affected foals, clinically normal foals, and adult horses. Therefore prevention of exposure is difficult. However, it is likely that clinically affected foals are the most common source of infection, through direct contact or common vehicle exposure. As a result, isolation of affected animals and the use of barrier precautions are the most important infection control measures. With the exception of disinfectants, protocols directed at control of *S. enterica* should be adequate for rotavirus control. Little specific information is available regarding the relative effectiveness of different disinfectants on equine rotavirus. However, as a nonenveloped virus, equine rotavirus should be expected to be resistant to environmental degradation and many disinfectants commonly used in veterinary medicine. The use of phenolics has been recommended because of their better activity in the presence of organic debris. Oxidizing agents probably have similar effectiveness and may be preferable because they have a much lower potential for toxicity.

46.10.5 Bovine Viral Diarrhea Virus and Border Disease Virus

The closely related members of the genus Pestivirus are not commonly considered nosocomial disease hazards, but this may be more because of a lack of detection than a lack of occurrence. The main infection control hazard is related to exposure of susceptible pregnant cattle, sheep, goats, or camelids to persistently infected animals that continuously shed large amounts of virus. The long period between infection of pregnant females and the birth of affected offspring complicates the ability to make relevant observations about the frequency of nosocomial infections. Therefore it may be important to encourage or require vaccination of valuable pregnant cattle or alpacas before admission. In addition, animals known or suspected to be persistently infected should be managed in isolation with barrier precautions to minimize transmission. This includes neonates showing signs of congenital infection. Increased biosecurity precautions should also be used with animals from herds with a recent history of disease related to these viruses. Direct contact with persistently infected animals is an efficient method of transmission, but limited research shows that calves can be infected through contact with contaminated stalls and through droplet or aerosol exposure over a distance of at least 1.5 m.[53] Appropriate use of cleaning and disinfection methods should readily decontaminate the environment.

1547 1548

46.10.6 Strangles *(Streptococcus equi equi)*

An important aspect of *S. equi* control is identification and management of subclinically infected animals. Syndromic guidelines for isolation on admission (e.g., isolation when patients are admitted from farms with recent a history of clinical *S. equi* infections, or isolation of horses with fever of unknown origin or unexplained nasal discharge) can help in managing potentially infectious horses so that they can be isolated pending the results of screening. The ubiquitous nature of *S. equi* and the possibility that essentially any hospitalized horse could be a subclinical carrier means that there is an ever-present, if low, likelihood of *S. equi* introduction into the hospital environment. Experience suggests that routine universal screening of horses admitted to veterinary hospitals is not necessary to control nosocomial *S. equi* infections. However, screening and isolation of horses from farms with endemic *S. equi* would be a reasonable control strategy. Standard infection control measures, including preventing direct contact of hospitalized animals, optimizing hand hygiene, and using appropriate cleaning and disinfection, should be useful for reducing the risk of *S. equi* transmission should a colonized horse be admitted. Vaccination in the face of an outbreak with vaccines that are currently available is not recommended because of a lack of proven efficacy and concerns regarding development of purpura hemorrhagica. There is also no evidence of a need to require vaccination of elective cases before hospital admission. *S. equi* is susceptible to all routinely used disinfectants, when used properly.

46.10.7 Equine Influenza

Influenza is one of the most contagious diseases affecting horses. Immunity is transient, and horses can be repeatedly affected during their lifetime. There is no carrier state, and maintenance in a population is dependant on transmission from one acutely infected horse to another. In horse populations aggregated at racetracks, shows, or other venues, attack rates can reach 15% to 30%.[54] The incubation period from exposure to onset of clinical signs is typically about 2 to 4 days, which commonly coincides with the onset of virus shedding. Horses are often febrile and obtunded at the onset of disease. Paroxysmal coughing is a classical sign of influenza infection that develops in some horses as disease progresses. Because of its contagious nature, identification of multiple acutely febrile horses can be an early indication that influenza virus is spreading in the population. Rapid identification and confirmation of animals shedding virus allow initiation of efforts to minimize contagious spread. Antigen detection assays are commercially available and very useful for rapid confirmatory testing (e.g., Directigen Flu A, BD Diagnostic Systems). However, these assays have limited sensitivity; virus shedding was detected in only approximately 30% of clinically affected horses during outbreaks using this assay, and so tests should be performed on multiple horses and interpreted in the aggregate for the population.[55] Negative test results for individual samples should be interpreted with caution because of the consequences associated with not using appropriate control measures during an outbreak of a highly contagious disease. PCR tests are available and may be more sensitive than antigen detection assays, but published validations of these assays are generally unavailable. Virus can be transmitted through aerosol, droplet, and contact transmission and can easily be transmitted over several feet in respiratory aerosols generated by coughing horses. Therefore horses confirmed to be infected should be managed in complete isolation with full barrier precautions, paying strict attention to hand-hygiene protocols. Influenza virus can survive on surfaces at most for a few days in a cool, moist environment. As an enveloped virus, influenza is susceptible to damage from extreme environmental conditions and is readily inactivated by all common disinfectants if they are properly applied. Although clinically affected animals are the most likely to shed large amounts of virus, in unaffected horses sampled during large outbreaks, seroconversion and virus shedding can be found in about 30% and 5% of the exposed populations, respectively.[54,55] Therefore it is prudent to increase infection control precautions for all

exposed but apparently unaffected horses in order to minimize risks of transmission. Early vaccination of all horses with intranasal vaccine may be of value in abbreviating the course of an epidemic. If new admissions are allowed when there is an elevated risk of influenza virus infection, horses should be required to have been recently vaccinated before admission (preferably a minimum of 2 weeks before admission) with vaccines having proven efficacy. Regardless of vaccination history, it is unwise to admit very young or immunocompromised horses when there is an increased risk of infection with influenza virus.

46.10.8 Equine Herpesviruses

Equine herpesvirus (EHV) types 1 to 5 are ubiquitous in horse populations and are highly contagious. EHV-1 and EHV-4 are the most widely recognized as important causes of outbreaks of disease in horses, and nosocomial transmission of both agents has been noted. EHV-4 infections are associated with contagious respiratory disease that principally affects horses under 3 years of age. EHV-1 infections are associated with respiratory disease, neurologic disease, acute to peracute pulmonary vasculitis, and abortion. Immunity is relatively short-lived, and infections are likely to occur throughout the life of horses. Many if not most of these infections are undetected or occur with only mild clinical signs. The most common clinical sequela of infection is mild respiratory disease during the first 2 years of life. Infrequently, EHV-1 infections can result in more severe complications such as abortions in pregnant mares or paralysis. All EHV-1 and EHV-4 infections originate in the respiratory tract, but epidemiologic evidence suggests that contact and droplet transmission between horses in relative proximity is much more common than aerosol transmission over greater distances. Fever is commonly the initial clinical sign exhibited by infected horses, and identification of multiple acutely 1548
1549
febrile patients can be an early indication of nosocomial spread of EHV in the population. Most horses can be shown to be latently infected with EHV-1 and EHV-4 by the time they reach adulthood, and subsequently any hospitalized horse might serve as a source of infection for other patients by recrudescing virus in response to stresses of disease, hospitalization, and transport. However, clinical experience suggests that nosocomial spread most commonly originates from clinically affected horses. Therefore, rapid identification of animals suspected of being infected, isolation of affected horses, and use of barrier precautions with appropriate hand-hygiene protocols are generally effective for minimizing the risk of nosocomial transmission. All horses exhibiting ascending weakness, paresis, or paralysis should be suspected of having EHV-1 infection and managed in isolation until they can be proven to have stopped shedding or another diagnosis is confirmed. Herpesviruses are enveloped viruses, and routine cleaning and disinfection procedures should be adequate for decontamination of surfaces, assuming appropriate protocols are followed. PCR testing of nasal secretions is the most useful assay for rapid confirmatory testing. Serial testing is useful for establishing that shedding has stopped. Without adjunctive testing, infected horses should be quarantined for a minimum of 28 days after cessation of disease. Using serial testing as a confirmatory adjunct, this quarantine period might be shortened to 14 days after cessation of disease. However, experimental infection studies have shown that shedding can be intermittent, and negative test results must be interpreted with caution.

EHV-3 is less commonly regarded as a nosocomial problem but has been noted to be spread through contact with contaminated materials during reproductive procedures as well as between horses during coitus. Therefore it is a notable hazard for practices that specialize in reproductive services. EHV-3 causes coital exanthema, a pustular disease affecting the vulva and vagina of mares and the penis and prepuce of stallions. Appropriate cleaning and disinfection of materials used in reproductive examinations, avoiding use of examination sleeves and gloves with multiple horses, and rigorous adherence to sound biosecurity precautions for breeding populations should control spread of EHV-3. The prevalence of latent EHV-3 infections is not well documented. Recently, evidence associating respiratory disease in young horses and EHV-2 or EHV-5 infection has been published,[56] but the significance of these agents in the occurrence of nosocomial disease is unknown.

46.10.9 Methicillin-Resistant *Staphylococcus aureus*

MRSA is emerging as an important veterinary and zoonotic pathogen. In large animals, MRSA infections have been most commonly identified in horses and pigs. Transmission of MRSA between these species and attending personnel can occur, and MRSA colonization and infection appear to be an emerging occupational risk associated with large animal veterinary practice. Transmission of MRSA is thought to mainly occur through direct or indirect contact between infected or colonized people or horses and hospitalized horses. Despite the potential for respiratory tract colonization, the potential for droplet and airborne transmission is minimal. The largest nosocomial infection problem related to this pathogen in large animals has been associated with the infection and colonization of equine patients. Infections are principally noted at surgical sites and wounds, whereas colonization predominantly occurs in the nasal passages, although gastrointestinal colonization has also been noted. If not identified by active surveillance, colonized horses can be silent yet prolific reservoirs for infection of humans and horses. Prevention of MRSA transmission requires careful attention to practices that prevent contact and common vehicle transmission, including use of good hand-hygiene practices, restriction of horse contacts and isolation of infected or colonized animals, and use of specific measures aimed at identifying carriers. All colonized or infected horses should be treated as infectious, housed in isolation, and handled with strict attention to contact barrier precautions. Screening by culture of nasal swabs collected at the time of admission can help control MRSA in areas where it is endemic in the community or the horse population. Screening of personnel may be required periodically if there is epidemiologic evidence of nosocomial transmission or zoonotic infections. Personnel screening can be a difficult and contentious area, so it is wise to develop screening guidelines in advance of an outbreak.[57] *S. aureus* is susceptible to most disinfectants, if used properly.

46.10.10 Coxiella burnetii

Coxiella burnetii is the causative agent associated with Q fever. Although most infections in humans are subclinical, personnel that contact livestock have a greater risk of infection, and disease can be severe and even fatal in a small portion of cases. It is also highly infectious, has a low infective dose, and can be transmitted through contact as well as by droplet and airborne routes. *C. burnetii* can be found in a variety of animal species, but zoonotic transmission is most commonly associated with periparturient ruminants (especially small ruminants). Serum antibody tests, antigen detection assays, and PCR assays can be used to identify infected animals, but the sensitivity of these assays has been questioned. Because of the potential significance of clinical infections in humans, all attending personnel should be appropriately aware of the zoonotic potential and risks associated with Q fever. The risk of serious clinical consequences should noted in particular by pregnant women and people with valvular heart disease or immunosuppression. Medical histories for individuals and flocks should be considered to determine if there is an indication that *C. burnetii* may be a greater than average risk. Biosecurity measures that could be used to minimize hazards to people with a high risk of clinical infection include isolating periparturient small ruminants, paying strict attention to hand-hygiene protocols, and using respiratory protection and barrier nursing precautions when handling potentially infected animals. Particular care should be taken during parturition and when handling aborted fetuses and newborn small ruminants. For animals known to infected, care should be used when cleaning and disinfecting stalls or other housing environments, and contaminated bedding and other materials should be handled with caution.

46.10.11 Antimicrobial Resistance and Drug Use

Although antimicrobials are undoubtedly required for proper management of a significant percentage of hospitalized large animals, it is reasonable to consider whether antimicrobial resistance and antimicrobial drug use affect the occurrence of or the ability to control nosocomial infections. The first relates to outbreaks of nosocomial infections with bacteria that are resistant to multiple antimicrobial drugs. These outbreaks are not extremely common but are a noted occurrence in human and veterinary hospitals and often occur in association with care in specific hospital units such as a critical care or surgery facility. Agents frequently identified in association with these outbreaks include enteric organisms such as *E. coli* and enterococci, skin commensals such as *S. aureus*, and *Pseudomonas* and other bacteria. Significant research into these organisms has identified 1549
specific strains and even specific genes that are commonly identified in association with agents responsible for 1550
these outbreaks (e.g., MRSA, vancomycin-resistant enterococci [VRE], bacteria with extended spectrum β-lactamase resistance). The role of antimicrobial use in specific patients or even in specific hospitals in promoting the occurrence of nosocomial outbreaks is not always conclusive. However, some experimental evidence does show that treatment with a specific antimicrobial drug is associated with an increased propensity for shedding of bacteria that are resistant to analogous drugs.[58] Therefore common use of a particular drug within a hospital could apply selective pressure that more generally promotes colonization with resistant bacteria,[59] or it could enable or promote the survival of specific bacterial strains capable of causing nosocomial epidemics (e.g., VRE and MRSA). These concerns are supported by specific documentation that antimicrobial drug exposure can be associated with increased likelihood of shedding of enteropathogens[60,61] and multidrug resistant pathogens.[62] In addition, antimicrobial drug exposure is a recognized risk factor for colitis in horses, which can be one of the most important infection control concerns in large animal facilities. Therefore efforts to reduce antimicrobial use and ensure logical (prudent) use can be beneficial to the individual patient and other hospitalized animals, in addition to addressing the more abstract concerns about emergence of antimicrobial resistance.[58] Surveillance aimed at benchmarking the use of antimicrobial drugs over time, or to monitor use for specific conditions or in specific circumstances (e.g., outside of regular hours), may be useful for guiding policy decisions, but it is not useful for identifying specific occurrences of “imprudent” use. Of greatest importance is education so that all individuals with prescribing power understand the issues and the reasons for careful antimicrobial use. Measures such as developing selection algorithms for patients with specific types of disease and restricting the use of certain drug classes (e.g., glycopeptides) have been used by some facilities and may decrease the likelihood of some occurrences of nosocomial infection.[59]

46.10.12 Management of Donor Animals

It is increasingly common to use animals owned by hospitals or veterinary personnel as donors for blood and ingesta (e.g., ruminal fluid) transfer to patients. Animals used for this purpose should be known to have a very low risk of contagious diseases, should be housed away from hospitalized patients, should be clinically healthy at the time of specimen recovery, and should be screened periodically for diseases that could be transmitted by use of transfer products. Diseases of concern that might be transferred by blood products from ruminants include bovine leukemia virus, bovine viral diarrhea virus and border disease virus, and anaplasmosis; similarly, horses should be screened for equine infectious anemia infection. Ingesta donors should be screened for Johne's disease *(Mycobacterium paratuberculosis avium)* and *S. enterica*.

47 Chapter 47 Prevention, Detection, and Response to Foreign Animal Diseases

Pam Hullinger

Perhaps one of the most critical roles that private veterinary practitioners play on a daily basis is serving as the nation's front line of defense against exotic, transboundary, and foreign animal diseases (FADs)—the important transmissible livestock or poultry diseases that are believed absent from the United States, but that if introduced would cause significant adverse animal health, public health, or economic consequences to the nation. Although many of these disease threats are known, new or "emerging" diseases may also enter the United States and affect human or animal populations. The U.S. Department of Agriculture (USDA) Animal and Plant Health Inspection Service (APHIS) has primary responsibility for addressing foreign and emerging diseases of livestock, and it works closely with state animal health officials, private veterinary professionals, and the livestock industry to conduct surveillance and detect, control, eradicate, or mitigate the impacts of these diseases on the industry and the public. A list of the diseases successfully eradicated from the United States is in Box 47-1. The *Code of Federal Regulations* (CFR), Title 9, part 53[1] details the federal government's list of reportable diseases of livestock and poultry and its policies and procedures for the diagnosis, appraisal, euthanasia, and disinfection of livestock and poultry infected with these diseases. The list specifically includes foot-and-mouth disease (FMD), rinderpest, contagious pleuropneumonia, exotic Newcastle disease (END), highly pathogenic avian influenza (HPAI), and infectious salmon anemia and generically includes "any other communicable disease of livestock or poultry that in the opinion of the Secretary constitutes an emergency and threatens the livestock or poultry of the United States." In addition to the federal list, many states require the reporting of additional disease conditions beyond those specifically listed in the CFR. Additional diseases specified by states may include diseases of public health importance, such as equine encephalomyelitis, or other domestic diseases of regulatory importance or interest, such as bovine trichomoniasis. Licensed, practicing veterinarians are responsible for maintaining a familiarity with the federal reportable disease list as well as those of the states in which they practice. The reportable disease list for each state can be obtained through the state veterinarian's office. States may also have their own more specific policies and procedures for the diagnosis, appraisal, euthanasia, and disinfection of livestock and poultry infected with such reportable diseases. Box 47-2 lists some reportable diseases of horses.

The Office of International Epizootics (OIE)[2] is an international organization, representing more than 167 member countries, that seeks to provide leadership and guidelines to ensure transparency and solidarity in the management of the global animal disease situation. The OIE publishes health standards for international trade in animals and animal products as well as criteria for the validation and certification of diagnostic assays. Policies and procedures that the federal government implements to manage the intrusion of FADs into the United States are often aligned with the OIE health standards and guidelines to help ensure the most rapid and efficient recovery of U.S. trading status. Another equally important function of the OIE is to provide an early warning system to enable countries to have rapid situational awareness and to act quickly to protect themselves when outbreaks of OIE reportable diseases are confirmed in member countries. More than 130 animal diseases are reportable to the OIE. It is important to remember that some of the domestic diseases that are present in the United States, such as bluetongue, are reportable to the OIE and have implications on trade with countries free of those diseases.

To protect the long-term, overall health and viability of U.S. animal agriculture, any incursion of a FAD must be rapidly identified and controlled. In the United States, ideally control leads to the eradication of the disease and full return to the status present before the outbreak. These FAD eradication efforts present significant short-term costs to affected industries as well as the government and the public. In some cases the effects become long term, lasting for years, and some industries may never fully recover. Most FAD incursions have a significant economic cost associated with disease control and eradication efforts. The costs associated with FAD control include the direct

costs of disease control as well as the potential loss of foreign trade and the indirect costs to the affected industries that result from the implemented control measures, such as livestock movement restrictions. Direct costs to the government include personnel costs, indemnity costs (cost to buy diseased animals from producers for destruction), and the cost of necessary supplies and equipment for euthanasia, carcass management, and disinfection. In addition to these direct control costs, one of the most immediate consequences of a FAD occurrence in the United States would be the loss of export markets and disruption of normal business continuity in the United States. The indirect costs to the affected livestock sectors and other affected industries that would result from the disruption of the normal business continuity are likely to be the most significant economic costs. One example of such an indirect cost or loss associated with disease control may be the reduction or loss of income for a dairyman who is no longer able to ship his milk across state lines to his customary processor. For all FADs, early detection and rapid application of situational awareness to assess the extent of the outbreak and efficiently implement necessary controls to minimize further spread will minimize the overall impact of the outbreak on the affected producers, the affected industries, and the U.S. economy as a whole.

47.1

Box 47-1 Years When Foreign Animal Diseases Were Eradicated from the United States

1892—Contagious bovine pleuropneumonia

1929—Foot-and-mouth disease

1929—Fowl plague

1934—Glanders

1942—Dourine

1943—Texas cattle fever

1959—Vesicular exanthema

1959—Screwworm (southeastern United States)

1966—Screwworm (southwestern United States)

1971—Venezuelan equine encephalitis

1973—Sheep scabies

1974—Exotic Newcastle disease

1978—Classical swine fever

1985—Highly pathogenic avian influenza

2003—Exotic Newcastle disease

2004—Highly pathogenic avian influenza

47.2

Box 47-2 Reportable Diseases of Horses*

African horse sickness

Contagious equine metritis

Dourine

Glanders *(Burkholderia mallei)*

Hendra virus

Japanese encephalitis

Piroplasmosis

Venezuelan equine encephalomyelitis

Vesicular stomatitis virus

* The list will vary by state.

The risk of a FAD incursion into the United States today is much greater than it was in the past. There are two main reasons for this. First, there has been a rapid expansion of international trade and travel, and in the ever-expanding climate of free trade, this can only be expected to continue. With a greater volume of people, animals, and animal products entering the United States on a daily basis, the opportunity for a FAD to be unintentionally introduced is greater. Second, in the wake of the World Trade Center bombing on September 11, 2001, there is heightened awareness and concern about the possibility of agroterrorism, or the deliberate introduction of a biologic agent targeting livestock for the purposes of causing economic damage and societal instability. Whether a FAD is

intentionally or unintentionally introduced, the detection of the first case as soon as possible is critical to minimizing the overall impact of the resulting outbreak.

Private veterinary professionals need to be familiar with the clinical signs associated with FADs, especially those that can be confused with signs of domestic diseases. When veterinary professionals are concerned about the possibility of a FAD, they need to know how to contact their federal or state animal health officials, who will consult with them on the history of the herd or flock, examine the affected animals, and take and submit necessary samples for testing at no expense to the producer or veterinarian. Testing will be prioritized by disease and level of concern. Both the producer and private veterinarian should be contacted with regular updates as test results become available. Hundreds of investigations such as this occur annually in the United States, and fortunately most lead to the determination that a FAD is not involved. It is the FAD that goes undetected or unreported for some time because of lack of vigilance that will cause major economic harm to the nation. Veterinary practitioners should not be concerned about reporting a suspected FAD and having it confirmed as a domestic disease problem, as it is important that the animal disease emergency response system be tested regularly to ensure that it is as efficient and effective as possible. Most important, the impact of a delay in detection of a true FAD could be catastrophic.

47.3 U.S. DEPARTMENT OF AGRICULTURE NATIONAL VETERINARY ACCREDITATION PROGRAM

The USDA established the veterinary accreditation program in 1907 to allow private practitioners to assist federal veterinarians in certifying animals for interstate and international movement and to assist in controlling animal diseases. The current mission of the National Veterinary Accreditation Program (NVAP) is to ensure the health of the nation's livestock and animal population and to protect the public health and well-being. NVAP's goal is to maintain the effective cooperation and use of private veterinary practitioners for regulatory work in a manner that is consistent with international trade requirements and safeguarding animal health. APHIS Veterinary Services (VS) administers NVAP. Participation in NVAP is voluntary and is not mandated by the federal government. A list of the requirements for a veterinarian wishing to become accredited by the USDA is shown in Box 47-3. Accredited veterinarians participating in NVAP must carry out their duties according to the Standards for Accredited Veterinarian Duties described in CFR Title 9, Part 161. Box 47-4 lists the standards for accredited veterinarians. USDA veterinary accreditation is specific to a given state, so one needs to contact the USDA APHIS VS office in the state in which he or she is practicing to ensure accreditation in that state. One requirement of USDA accreditation is the reporting of all suspected FADs to state or federal animal health officials for evaluation and testing if necessary. Box 47-5 lists some of the clinical signs that should alert a private veterinarian that a foreign animal disease should be considered.

Accredited veterinarians are the backbone of U.S. regulatory programs for livestock and poultry diseases. The responsibilities of an accredited veterinarian are extraordinary. In fact, the United States depends extensively on accredited veterinarians for many official functions (e.g., inspecting, testing, and certifying animals). Livestock producers who ship animals domestically or export animals internationally rely on the expertise of accredited veterinarians to help ensure that exported animals meet the requirements of the receiving location and will not introduce diseases into the receiving state or country. The accreditation program has served the animal industry well for many years and remains integral to its continued growth. There are currently more than 60,000 active accredited veterinarians in the national database, and these accredited veterinarians are instrumental in providing national capability to perform competent health certifications and to maintain extensive disease surveillance and monitoring. Today, more than 80% of all U.S. veterinarians are accredited and work cooperatively with federal and state animal health officials in NVAP.

47.3.1

Box 47-3 U.S. Department of Agriculture Accreditation Requirements

Graduate from an AVMA-accredited school.

Attend an accreditation seminar.

Submit accreditation application to the appropriate U.S. Department of Agriculture (USDA) Veterinary Services (VS) office.

Be licensed and accredited in each state in which you plan to perform official work.

47.3.2

Box 47-4 Standards for Accredited Veterinarians (9 Code of Federal Regulations, 161.3)

Immediately report program diseases.

Know current regulations.

Perform activities according to regulations.

Accurately complete all forms.

Personally inspect all animals.

Properly identify reactors.

Maintain proper biosecurity.

Use regulated materials according to the regulations.

Maintain security of official tags, forms, and certificates.

47.3.3

Box 47-5 Clinical Signs or Observations That Indicate a Foreign Animal Disease Should Be Considered

Vesicles in oral cavity or around coronary bands

Central nervous system signs

Mucosal diseases

Hemorrhagic septicemias

Larvae in wounds

Unusual (ornate) ticks

High morbidity or mortality

Unusual or unexplained illness or symptoms

The accreditation process has changed dramatically over the years. In the 1980s and early 1990s veterinarians were required to pass a written examination, but currently accreditation requires only attendance at a seminar at which the responsibilities and requirements for accreditation are discussed. Attendance at such a seminar provides for lifetime accreditation as long as one does not practice in a new state. Concerns have been raised that this process does not enable private veterinarians, who are the first line of detection of FADs, to keep current on FADs and the world animal disease status. Many recent efforts have focused on enhancing private veterinarians' awareness of their important role in FAD surveillance. In addition, in June 2006 a notice was published in the *Federal Register* proposing changes to the existing NVAP program. These included the implementation of two different categories or levels of accreditation. These changes are being proposed to help ensure that all accredited veterinarians have the tools needed throughout their careers to meet the evolving challenges of FAD prevention and preparedness in the United States.

47.4 OVERVIEW OF A FOREIGN ANIMAL DISEASE INVESTIGATION AND RESPONSE

Protecting the nation's livestock and poultry industries from FADs involves four basic principles or phases of emergency management. They are prevention, preparedness, response, and recovery. To be effective these phases require support, cooperation, and communication among individuals, groups, and organizations at the local, state, regional, and national levels. Livestock and poultry owners; veterinarians in private clinical practice; industry groups; the federal, state, and local governments; state universities; veterinary diagnostic laboratories; and the public must all be included in emergency response preparation and planning. A response to a FAD outbreak would be carried out in accordance with the guidelines established by the National Response Plan (NRP) and using the National Incident Management System (NIMS) and the Incident command system (ICS). Veterinarians who are interested in participating in either animal disease or disaster emergency response efforts, either as temporary employees or as volunteers, need to be familiar with these systems before an event occurs, in order to effectively integrate into the response effort. There are both online and classroom-based training programs offered by federal, state, and local emergency response agencies. The Federal Emergency Management Agency (FEMA) offers several Web-based, self-paced courses.[3]

Although the details of the clinical signs and epidemiology of the FADs themselves are discussed in detail in other sections of this book, there are many additional references and resources available to practicing veterinarians to help them keep apprised of the clinical presentation and importance of these diseases as well as to whom to report suspected cases. Two excellent references for disease-specific information are *Foreign Animal Diseases: "The Gray Book,"* revised 1998,[4] available at http://www.vet.uga.edu/vpp/gray_book02/index.php, and the website of the Center for Food Security and Public Health of Iowa State University,[5] http://www.cfsph.iastate.edu.

47.5 ## PREVENTION AND PREPAREDNESS

Early recognition of a FAD can be difficult because many domestic diseases seen by veterinarians on a routine basis have clinical signs that are similar to those of a FAD (e.g., FMD) and because a FAD may have mild clinical signs that may allow it to spread undetected for some period of time (e.g., low pathogenic form of classical swine fever [CSF]). Examples of both domestic and foreign vesicular or ulcerative diseases which may be difficult to distinguish clinically in cattle are presented in Box 47-6. A similar list for small ruminants is provided in Box 47-7. The increased threat status and severe consequences of the introduction of a FAD into the United States require private veterinarians to be continually vigilant for unusual emerging animal health conditions. In order to be best prepared to identify these rare disease conditions, veterinary practitioners must understand how they may manifest and what clinical signs they may possess. Participation in continuing education programs aimed at increasing awareness of the clinical signs of FADs can facilitate the necessary awareness. Education and awareness should also be extended to producers and their employees who will likely be the first individuals to recognize a problem in the herd or flock with which they work on a daily basis.

Bluetongue

Contagious ecthyma (ORF)

Epizootic hemorrhagic disease (EHD)

Note: Reportable diseases are highlighted in bold.

Another important component of the prevention of FAD incursions is the implementation by APHIS of policies and procedures related to the importation of animal species or products into the United States These rules vary by animal and product, as well as by country of origin. APHIS monitors the OIE reports of the world animal health status and continually updates the importation requirements accordingly. These requirements may dictate the quarantine and possible testing of specified animal species for specific periods of time before the animals are allowed to enter the United States. As of 2007 there were four import centers, located in New York, Miami, Los Angeles, and Honolulu, through which such animals could enter the country legally. Illegal importation of such animals and animal products via other channels poses a significant risk to U.S. agriculture. APHIS port veterinarians are responsible for the examination of the animals, their identification, and evaluation of health certificates and permits for accuracy at the importation stations. If the requirements are not met or the animals are found to be diseased, then the animals are refused entry. Once it has been determined that an animal is healthy, all the test results are negative, and all the requirements have been met, then the animal can be released to its owner and the state of destination is notified of the animal's movement into that state.

47.6

DETECTION

Although border controls and import procedures have historically been largely effective in keeping FADs out of the United States, there is always the possibility that a FAD could appear in this country by either unintentional or intentional means. The responsibility for rapidly detecting and effectively responding to incursions of FADs is

primarily that of APHIS in cooperation with livestock and poultry owners, veterinarians in private clinical practice, and state animal health officials. An additional challenge for early detection of FADs is that there are very few ongoing surveillance programs that routinely test for FADs in targeted, high-risk livestock populations or in conjunction with screening for clinically indistinguishable domestic diseases in state or regional animal diagnostic laboratories. Because many of the FADs can mimic domestic diseases, a FAD may not be properly identified for some time if the condition is believed to be a domestic disease problem and if it is investigated with that primary differential in mind without initiating testing for a FAD. Even a single day's delay in identifying a FAD can result in significantly greater disease spread owing to the large amount of livestock movement that occurs in the United States on a daily basis. Prompt reporting, investigation, and diagnosis can prevent a FAD from spreading, can reduce the overall economic cost of the event, and can reduce the likelihood that the disease may become endemic in a wildlife or arthropod reservoir.

The most likely person to initially suspect a FAD is the producer or private veterinarian called by the producer to investigate the unusual disease condition. It is critical that any time a FAD is suspected it is reported to state or federal animal health officials for expedited investigation and testing as necessary. The state animal health official, usually the state veterinarian, and federal veterinarians working for USDA APHIS VS routinely work to increase awareness of such conditions and reporting information among the state's private veterinarians and livestock producers. These activities require the support and assistance of state veterinary diagnostic laboratories, the Cooperative Extension Service of the USDA, state and federal meat and poultry inspection services, universities, animal scientists, market operators, and livestock and poultry producers and their private veterinarians.

For FAD outbreaks to be detected quickly, any suspicious signs of a FAD must be promptly reported to the state veterinarian, the USDA VS federal veterinarian, or both so that a FAD can be confirmed or ruled out. Private veterinarians are knowledgeable regarding the occurrence of various domestic animal diseases in their practice area and the history of such diseases on their clients' farms and ranches. This type of historical information and a herd's vaccination and animal movement history are critical to assessing the likelihood of a suspected FAD. Working with the herd veterinarian and the producer, the investigating state or federal, specially trained FAD diagnostician (FADD) will use the herd history and clinical investigation to assess the likelihood that the situation involves a FAD and to determine the appropriate sample(s) to collect, the method of sample delivery, and what precautions must be taken at the site while test results are pending. Specimens are submitted to the National Veterinary Services Laboratories (NVSL) in Ames, Iowa or to the Foreign Animal Disease Diagnostic Laboratory (FADDL) in Plum Island, New York to confirm the presence or absence of a FAD. On the basis of initial FAD investigation findings, often before the laboratory has completed testing of the samples, state and federal officials in the affected state may take action to quarantine affected animals or poultry at the site of the suspected case, increase surveillance in the area, and initiate steps to gather further information to assess the situation and characterize and control the outbreak if necessary.

One of the disadvantages of the current system is that there may be a 1- to 2-day delay in obtaining a diagnosis when an affected animal is located in a state distant to FADDL in New York. An additional disadvantage is that FADDL does not do routine testing for domestic diseases. Therefore, under the current system, domestic disease testing often cannot be initiated until the FAD is ruled out. This delay in domestic disease diagnosis may be a disincentive for a private veterinarian to involve a FADD in the process when his or her clinical judgment is that the likelihood of a FAD is low. One possible solution to this situation would be to allow select, trained, proficiency-tested state or regional veterinary diagnostic laboratories to run screening tests for FADs; positive results could then be confirmed at FADDL. This would allow domestic disease testing to occur in parallel with FAD surveillance. The USDA is currently working with the National Animal Health Laboratory Network (NAHLN) to proficiency-test and transition some of the screening tests for FADs to approved laboratories. At

1554 1555

present only assays for CSF, HPAI, and END have been successfully transitioned to some of the NAHLN laboratories for use in national surveillance programs. Although there is a singleplex polymerase chain reaction (PCR)–based FMD assay slated for deployment to proficiency-tested NAHLN laboratories, it has not yet been deployed for routine use in any of the laboratories.

Other diagnostic tools that may be available in the near future include deeply multiplexed nucleic acid, antibody, or protein assays that could allow the simultaneous screening for many disease agents in one reaction for a reduced cost per agent. Although these types of assays are still undergoing development and validation in the veterinary community, similar assays are in use as part of the BioWatch program, which is a human biothreat agent surveillance system operated by the Centers for Disease Control and Prevention in Atlanta, Georgia. Once validated, such assays could become useful components of targeted surveillance programs in the United States.

47.7 RESPONSE, MANAGEMENT, AND CONTROL

A FAD response will be conducted according to the guidelines set forth in the NRP. This response plan incorporates best practices and procedures from various emergency management disciplines and integrates them into a unified structure that forms the basis of how the federal government coordinates with state, tribal, and local governments and the private sector during all incidents, including animal disease outbreaks. Under the NRP the USDA is the lead agency coordinating the protection of agriculture and natural resources. All national responses are conducted in accordance with NIMS, which established a national emergency response framework to allow local, state, tribal, and federal agencies to more efficiently and quickly work together in an emergency. The NIMS uses the ICS to organize the response. The ICS is designed to be expandable and to meet the needs associated with incidents of all sizes, to allow individuals from a variety of agencies to meld more efficiently into a common management structure, to be cost-effective by reducing duplication of effort, and to provide needed logistic, administrative, and operational staff. There are five main management functions in the ICS: incident command, operations, planning, logistics, and finance and administration. Most veterinarians work in the operations or planning sections during a FAD response. The operations section is where the bulk of the tactical field work is conducted, such as diagnosis, surveillance, and depopulation.

Once a FAD has been confirmed by the USDA, the notification and coordination process for all involved parties begins. This includes federal, state, international, local, industrial, and public stakeholders. Conference calls, electronic notification, and press conferences may be used to communicate key messages. In addition, if agroterrorism is suspected, the Federal Bureau of Investigation and the Department of Homeland Security will be involved in the response efforts. If a zoonotic disease is suspected, then the state and federal public health departments will also become involved. Federal officials will notify the OIE of the situation so that the international communities will be made aware of the change in the nation's animal health status. Throughout the response the goal will be to maintain accurate, timely communications regarding the status and progress of the eradication efforts.

When the diagnosis of the initial case is confirmed, there is still much information to be gathered to determine the true magnitude of the situation. The species affected, history of the diseased herd or flock (including recent animal movements), and stage of disease in the affected animals will provide valuable information regarding the likely extent of disease. Outbreaks can be large or small, simple or complex, and localized or widespread. Timely development of situational awareness will be critical for mobilizing the necessary resources to effectively respond to the situation.

Tactical measures or procedures employed to control an outbreak may include quarantine and/or animal movement restrictions; biosecurity; epidemiologic investigations; surveillance for disease in surrounding areas;

vaccination, euthanasia, or treatment of affected animals; carcass disposal; disinfection; vector control; and education campaigns. The exact approach to control will vary by disease, affected region, and extent of the outbreak. In many cases federal and state veterinarian resources will be sufficient to respond to and control the situation quickly. However, if the outbreak is large or widespread it may require the use of additional personnel resources.

When APHIS requires temporary personnel to assist with disease eradication, it uses the National Animal Health Emergency Response Corps (NAHERC), a roster of private veterinarians and animal health technicians, to assist with the control efforts. Private veterinarians may be enlisted to examine herds or flocks for clinical disease, vaccinate animals, collect laboratory samples, perform necropsies, collect epidemiologic data, and euthanize infected animals. During the United Kingdom's 2001 FMD epidemic, many private veterinarians found that their clients stopped using their routine services as a precaution to reduce the chances that their farms would become infected, and in other cases clients' farms were lost to disease control efforts. In many cases these veterinarians joined the FMD task force as Temporary Veterinary Inspectors (TVIs) working on behalf of the British government to assist in the control of the epidemic for some period of time. U.S. veterinarians interested in registering for NAHERC should contact their state USDA APHIS VS office or go to the NAHERC website for details.

47.8 RECOVERY

The goal of the recovery process is to return the nation to a status equal to or better than what existed before the FAD outbreak. Full recovery can be a long and arduous process. Recovery activities include payment for animals and materials destroyed for disease control purposes, successful cleanup and restocking of affected premises, renegotiation and reestablishment of international trading status, and government and industry's reassurance to the consumers and the public that the outbreak has been managed successfully. The OIE's international animal health code sets the standards that determine when a country will be classified as disease-free. The OIE standards, which must be satisfied before resumption of international trade, serve to reassure the international community that trading with a previously affected country is now safe.

The ultimate cost of an outbreak for a country, its producers, affected industries, and the public can be quite high. Many of the costs beyond those to the directly affected industries can be significant yet difficult to quantify.

1555

1556

47.9 THE FUTURE OF FOREIGN ANIMAL DISEASE DETECTION AND RESPONSE

A comprehensive review of the national framework for addressing animal diseases was conducted by a committee assembled by the National Academies and published in 2005.[4] The committee's findings and recommendations support the compelling need for significant changes to create a new future for animal health in the United States. Some of the key findings included the need for new tools for detection, diagnosis, and risk analysis and the expansion of the NAHLN's capabilities for both routine and emergency diagnostics. The committee called for the colleges of veterinary medicine to lead an effort to develop a national animal health education plan to educate and train individuals from all sectors in disease prevention and early detection and to recruit veterinary students into careers in public health, food systems, biomedical research, diagnostic laboratory investigation, pathology, epidemiology, ecosystem health, and food-animal practice. As animal health has broad implications, ranging from the health of individual animals and the well-being of human communities to issues of global security and the adequacy of the global food supply, there is significant need to plan carefully for the future. The committee concluded that given the changing nature of the risks to animal health in this country, it is unlikely that the current philosophy on how to protect animal health will be adequate in the future.

Extraordinary changes including continued globalization will continue to present new threats to U.S. agriculture and necessitate the continued vigilance of the veterinary and agricultural communities. While state and federal governments are working to provide more targeted, active surveillance programs, private veterinary practitioners, who on a daily basis provide health care to the national herd, will remain the core of the nation's early warning system for FAD surveillance. Therefore their awareness of FADs and willingness to serve in the critical role of being part of the nation's early warning system for FADs will continue to be a cornerstone of national defense against the intrusion and the devastating impact of such diseases.

48.1 EQUINE VACCINATION AND INFECTIOUS DISEASE CONTROL

W. David Wilson

Nicola Pusterla

48.2 GENERAL CONSIDERATIONS

Programs for controlling infectious diseases are important components of management practices directed toward maximizing the health, productivity, and performance of horses.[1] Infectious disease in an individual horse or an outbreak of infection in a group occurs when horses experience challenge with an infectious agent at a dose sufficient to overcome resistance acquired through previous natural exposure to the disease or through vaccination. For this reason, programs for controlling infectious diseases should have the following three goals:

1. To reduce exposure to infectious agents in the horses' environment
2. To minimize factors that diminish resistance
3. To enhance resistance through the use of vaccines (vaccination alone cannot be expected to prevent disease; management practices must reduce challenge with infectious pathogens)

The incidence of infectious disease in horse populations tends to rise with an increased number and stocking density of susceptible horses at a facility, with movement of horses on and off the facility, and with favorable external environmental and management influences. Other factors that influence the risk of acquiring infection and developing disease include the age, type, breed, gender, and use of the animals; geographic, climatic, and other environmental factors; facilities' layout and management practices; and history of exposure to or vaccination against individual diseases.

The conditions on breeding farms, in performance and show horse barns, and at racetracks are ideal for the introduction and transmission of infectious diseases, particularly those of the respiratory tract. On breeding farms, the introduction and commingling of horses of various ages and origins and the high proportion of young, susceptible horses and pregnant mares create a situation that poses special problems and demonstrates some important considerations in the practice of disease control. The risk of acquiring infection can be reduced by maintaining distinct groups by age and function. Resident mares and foals should be kept separate from weanlings, yearlings, horses in training, and visiting mares. Visiting mares and other horses entering the farm should have a negative Coggins test result for equine infectious anemia (EIA) and should be appropriately

vaccinated and dewormed before arrival. They should be received and maintained in barns and paddocks separate from the resident farm population. Preferably a specific group of caretakers should attend to incoming horses; and footbaths, separate equipment, and a clean change of coveralls and boots should be used.

New arrivals should be quarantined for 30 days and monitored for signs of contagious disease. The rectal temperature should be recorded at least once daily, and any prophylactic procedures not done before arrival should be performed. Foaling mares being sent to a distant breeding farm for breeding should be transported 6 to 8 weeks before foaling; this permits timely exposure to resident pathogens at the destination farm, which allows the mare's immune system to mount a response and concentrate antibodies in the colostrum to improve passive protection of the foal. Mares being shipped short distances for breeding can be transported during estrus and returned to the farm on the same day to reduce the risk of the foal acquiring infection.

Regardless of the type of equine facility, any horse that becomes ill with a possibly contagious disease should be isolated, preferably in an air space separate from the remainder of the herd, for at least 10 days beyond complete abatement of clinical signs. Separate equipment should be used, and if a separate group of caretakers is not available for these animals, workers should always complete their work with healthy horses before handling sick horses. Caretakers should wash their hands and boots thoroughly between horses and wear different outer clothing or coveralls. Stalls that have housed sick horses should be cleaned thoroughly, disinfected, allowed to dry, and left empty as long as possible. This approach is particularly important in dealing with organisms such as *Streptococcus equi* that can survive in a protected, moist environment for several weeks.[2]

In most equine enterprises, vaccination is important to the overall management program for controlling infectious diseases. No “standard” vaccination program can be recommended for all horses; each situation must be evaluated individually by weighing the risk of acquiring infection and the medical and economic consequences of infection against the cost and expected efficacy of the product or products being considered for inclusion in the program, and their potential for inducing adverse reactions. Cost should include expenses incurred and money lost during the time the horses are out of competition, labor and medication expenses if the animals develop clinical disease and require treatment, and the expenses in time, labor, and vaccines required for proper immunization. The client's expectations should be realistic, and the veterinarian should explain the following points carefully:

1557

1558

- Vaccination minimizes the risk of infection but does not prevent disease in all circumstances.
- The primary series of vaccines and booster doses should be administered appropriately before likely exposure.
- Horses in a population are not all protected equally nor for an equal duration after vaccination.
- Whenever possible, all horses in a herd should be vaccinated on the same schedule; this simplifies record keeping, minimizes replication and transmission of infectious agents in the herd, and optimizes herd immunity by protecting those animals that responded poorly to vaccination.

A properly administered, licensed product should not be assumed to provide absolute, effective protection during any given field epidemic. Copies of the vaccination and health maintenance records should accompany each horse leaving the facility for sales, training, or breeding. Similarly, owners of equine facilities should establish prerequisites for vaccination of all horses entering the facility and request that copies of the vaccinal records accompany those horses.

Client expectations and the goals of disease control programs vary considerably. In performance horses, the goal generally is to minimize time spent out of training and thereby to maximize earning potential. In this case an

enforced period of rest owing to infectious disease has much more profound economic consequences than a similar recommendation for a barren broodmare or backyard horse. On the other hand, many owners of backyard horses diligently vaccinate against even low-risk diseases, despite the expense involved, to keep their horses healthy.

Only federally licensed vaccines should be used, and strict attention must be paid to the manufacturer's recommendations for storage, handling, and routes of administration to maximize the product's efficacy and safety. However, research or clinical experience may support alternate protocols for vaccination that will improve the vaccine's efficacy without increasing adverse effects. The length of time needed to induce a protective immune response should be considered in relation to expected exposure. For instance, when inactivated (killed) vaccines are administered by intramuscular injection, optimal protection generally is not achieved until 2 to 3 weeks after completion of the primary series or 1 or more weeks after administration of a booster dose. Inactivated vaccines administered intramuscularly (IM) generally induce a greater serologic response when an initial series of three doses is given rather than the two-dose series recommended by most vaccine manufacturers.

The primary role of authorities charged with licensing vaccines in North America traditionally has been to ensure the purity and safety of the vaccines, with less emphasis placed on documentation of efficacy.[3–5] Consequently, little published information was available in the past documenting the efficacy of most vaccines licensed in North America. Thankfully, the situation has improved substantially in recent years, to the extent that published efficacy data are available for almost all equine vaccines licensed in North America since 1999.[6–18] Field experience and some experimental evidence suggest that the efficacy of vaccines directed against different diseases varies considerably and that efficacy also varies among the vaccines from different manufacturers directed against the same disease.[8,19,20]

Vaccination is unlikely to confer protection more durable than that produced by recovery from natural disease, especially when the route of vaccination (usually intramuscular) is different from the route of natural infection; this is because vaccines frequently do not evoke the full array of protective immune responses induced by natural infection.[21,22] For example, the efficacy and durability of protection induced by parenteral vaccines against respiratory tract pathogens are frequently questioned.[4,5,22] In part this reflects the fact that parenterally administered vaccines generally are poor inducers of the local mucosal immune responses that are important for effective protection against infection of the respiratory tract.[4,21,22] In addition, immunity achieved after natural infection with some respiratory tract pathogens is short-lived.

48.2.1

Vaccination of Foals and Influence of Maternal Antibodies on Vaccine Responses

Maternally derived antibodies (MDAs) and perhaps other immune effectors such as lymphocytes that are concentrated in colostrum and are passively transferred to the foal play a crucial role in defense against pathogens encountered during the first few months of life while endogenous immune function continues to mature. Passive transfer of MDAs should therefore be exploited in immunization programs for foals by consistently administering booster doses of selected vaccines to mares 4 to 8 weeks before foaling and by ensuring that foals ingest adequate amounts of high-quality colostrum within 24 hours of birth. In addition to passively protecting the foal, MDAs may also exert a profound inhibitory effect on the active immune response of the foal to antigens, including those contained in vaccines. This phenomenon is known as *maternal antibody interference*.

Several studies reported during the 1990s brought this issue into focus by demonstrating that foals less than 6 months of age consistently failed to mount serologic responses to inactivated influenza vaccines.[23–29] Of potentially greater concern was the finding that a high proportion of foals vaccinated under the cover of MDAs not only failed to seroconvert in response to the recommended primary series of two or three doses of influenza vaccine, but many also failed to respond to multiple additional doses administered during the next year, suggesting induction of a potentially detrimental "immunotolerance-like" phenomenon.[26,27,30] Our studies confirmed an apparent lack of response of foals to multiple doses of inactivated influenza vaccines when the hemagglutination inhibition (HI) test was used to detect serologic responses, but responses were detected when the same samples were assayed using sensitive isotype-specific enzyme-linked immunosorbent assay (ELISA). Rather than representing true tolerance, it appears that MDAs may cause misdirection of the immune response away from the more important virus-neutralizing (VN) IgGa and IgGb subisotypes in favor of the less effective IgG(T) subisotype of IgG.[23] Subsequent studies in which titers of total rather than antigen-specific IgG subisotypes were determined documented that the age-related increase in concentrations of IgGb lagged significantly behind increases in concentrations of other isotypes and remained below adult levels beyond 6 months of age.[31]

Maternal antibody interference has now been documented to be a significant issue for many other antigens, including tetanus, eastern equine encephalomyelitis (EEE), western equine encephalomyelitis (WEE), and equine herpesvirus types 1 and 4 (EHV-1 and EHV-4), contained in vaccines administered to foals.[23,32–36] 1558
Even low levels of antibody, below those detectable by many routine serologic tests and below those thought to 1559
be protective, can completely block the serologic response to some vaccines, resulting in a potentially prolonged period of susceptibility before the foal is capable of responding appropriately to vaccines.[35] These findings also indicate that it is not typically feasible to test samples from foals serologically to predict whether they will respond to particular vaccines. We now recommend that primary immunization with most vaccines containing inactivated antigens should be delayed until foals are 6 months of age or older and that, with the exception of rabies vaccine, three doses of vaccine should be included in the primary series rather than the two doses routinely recommended by vaccine manufacturers. Typically, the third dose stimulates a serologic response of greater magnitude and durability than two doses and may also contribute to a higher "set point" for the response to subsequent booster doses.[23,35,37,38] In contrast to the results cited previously, maternal antibodies do not appear to exert a marked inhibitory effect on the response of foals to either the inactivated or recombinant live West Nile virus (WNV) vaccines (West Nile-Innovator, Fort Dodge; Recombitek, Merial), thereby permitting antibody-positive foals as young as 3 months of age to be immunized successfully.[37]

Study results should be interpreted with caution because only humoral responses are typically assessed and infectious challenge is not performed to confirm that lack of serologic response equates to lack of protection. Lack of a serologic response may correlate well with lack of protection for some diseases and some vaccines, whereas for others this may not be the case. In contrast, the presence of a serologic response may not correlate well with protection, as is frequently the case for respiratory tract pathogens. With the exception of the intranasally (IN) administered strangles and influenza vaccines (Pinnacle IN, Fort Dodge; Flu Avert IN, Intervet), the modified live virus EHV-1 vaccine (Rhinomune, Pfizer), the modified live virus EVA vaccine (Arvac, Fort Dodge), and the canarypox-vectored WNV and influenza vaccines (Recombitek, Merial), most commercially available vaccines are inactivated, adjuvanted, and administered by intramuscular injection (Table 48-1). Because inactivated vaccines administered by injection have limited potential to stimulate cellular and mucosal responses, serologic responses to these vaccines likely correlate well with their potential to induce protection. In turn, MDA interference with serologic responses to inactivated vaccines likely equates to failure to induce protection. In contrast, failure to detect a serologic response to a modified live, vectored, DNA, or

mucosally administered vaccine may not equate to lack of protection because vaccines of these types induce a broader array of systemic and local responses that may not be affected by MDAs.

Table 48-1 Types of Equine Vaccines Commercially Available

	Dead Vaccines		Live Vaccines		
Disease	Inactivated	Subunit	Modified Live	Recombinant	DNA Vaccine
Tetanus		X			
Western equine encephalitis	X				
Eastern equine encephalitis	X				
Equine Venezuela encephalitis	X				
West Nile virus	X			X, X (chimera)	X
Equine influenza	X		X	X	
Equine herpesvirus 1	X		X		
Equine herpesvirus 4	X				
Strangles		X	X		
Equine viral arteritis			X		
Rabies	X				
Potomac horse fever	X				
Botulism		X			
Equine protozoal myeloencephalitis	X				
Rotavirus	X				

If maternal antibody interference were not an issue, the approach to vaccination of foals would be greatly simplified because primary vaccination against all important diseases could be completed before MDAs had declined to nonprotective levels. In effect, the “window of susceptibility” would be eliminated. In reality, an attainable goal is to maximize the beneficial effects of MDAs while minimizing their negative impact on primary immunization. In order to best meet this goal, one or both of the following should be determined to be the primary focus:

1 To protect the foal and weanling against specific high-risk infectious diseases that affect this age group and have the potential to cause significant disease, either directly or by predisposing to other secondary infections

2 To initiate primary immunization to protect against disease later in life

Assessing risk takes into account both the likelihood that the foal will become infected as well as the risk of serious sequelae or death if the horse does become infected and develop disease. If the disease affects the foal

early in life, such as is the case with rotavirus (RV) infection, there is usually insufficient time to induce a protective immune response by actively immunizing the foal. Under these circumstances, the approach should be to maximize the degree of protection passively transferred from the dam via colostrum. Other diseases, such as rabies, affect horses of all ages, but the risk of acquiring infection is generally low.

48.2.2 Diseases of Moderate to High Risk to Young Foals but Low Risk to Adults

Diseases of moderate to high risk to young foals but low risk to adults include RV infection (on certain breeding farms in certain years) and, in geographic areas such as Kentucky and some other eastern states, type B botulism. For these diseases, the following approach is appropriate: 1559 1560

- Booster-vaccinate the dam before foaling to maximize uniformity of passive transfer.
- Ensure good passive transfer of maternal antibodies.
- Introduce management practices to reduce exposure to the infectious agent.
- Vaccinate the foal if risk continues beyond the first few months of life.

48.2.3 Diseases of Moderate to High Risk for Weanlings and Older Horses but Lower Risk to Young Foals Born to Vaccinated Mares

Diseases of moderate to high risk for weanlings and older horses but lower risk to young foals born to vaccinated mares include EHV-4, EHV-1, strangles, influenza, tetanus, EEE, and WNV infection. For these diseases, the following approach is appropriate:

- Vaccinate the dam before foaling to maximize uniformity of passive transfer.
- Ensure good passive transfer of maternal antibodies.
- Start foal vaccination after the risk of maternal antibody interference is no longer present in *most* foals. When several vaccine types are available for a particular disease, the vaccine that is least subject to MDA interference should be used. Introduce management practices to reduce exposure to the infectious agent while primary vaccination is being completed.
- If a two-dose primary series is recommended for adult horses, use three or more doses of vaccine in the primary series to improve the chances that foals that do not respond to earlier doses will respond to additional doses administered later.

48.2.4 Diseases of Low Risk to Foals

Diseases of low risk to foals in most circumstances include rabies, Potomac horse fever (PHF), WEE, and equine viral arteritis (EVA). For these diseases, the following approach is appropriate:

- Vaccinate the dam before foaling if the disease is a significant risk to adult horses and a vaccine shown to be safe for use in pregnant mares is available. If the available vaccines are not considered safe for use in pregnant mares, administer boosters before breeding.
- Ensure good passive transfer of maternal antibodies.

- Start foal vaccination after the risk of maternal antibody interference is no longer present in *any* foal (typically 9 months to 1 year of age).

48.2.5 Adverse Reactions to Vaccines

Although uncommon, the possibility always exists for adverse reactions (including anaphylaxis) associated with administration of a vaccine; therefore vaccines should be administered by or under the direct supervision of a veterinarian. Adverse reactions should be reported to the vaccine's manufacturer and to the U.S. Department of Agriculture (USDA) (1-800-752-6255) or the U.S. Pharmacopeia (USP) Veterinary Practitioners Reporting Program (forms may be obtained or reports submitted by calling the USP at 1-800-487-7776). Anaphylaxis constitutes a life-threatening emergency requiring prompt treatment with epinephrine (3 to 5 mL of a 1:1,000 dilution IM or 5 mL of a 1:10,000 dilution slowly intravenously [IV] for a 450-kg horse). Repeated doses of epinephrine can be administered at 15-minute intervals if necessary.

Local irritant tissue reactions occur more frequently, particularly when polyvalent combination vaccines and injectable strangles vaccines are used. These reactions usually are self-limiting, but resolution can be promoted by parenteral or oral administration of nonsteroidal antiinflammatory drugs (NSAIDs), topical application of warm compresses or the cutaneously absorbed NSAID diclofenac (Surpass, Idexx Pharmaceuticals, Greensboro, NC), and gentle exercise. Significant reactions in the neck muscles may make the horse reluctant to lower or raise its head; therefore feed and water buckets should be positioned accordingly. The occurrence of externally visible local reactions can be reduced by administration of the vaccine deep in the semimembranosus and semitendinosus muscles of the hind leg rather than in the neck and by allowing the horse to exercise after vaccination. In addition, horses that repeatedly react to polyvalent vaccines may benefit from administration of an NSAID before vaccination, from administration of the individual antigenic components separately in different sites, from use of a different brand of vaccine, from use of a vaccine that can be administered by a route other than IM, or from use of a vaccine that contains a different adjuvant or no adjuvant at all.

Some horses develop transient, self-limiting systemic signs that may include fever, anorexia, lethargy, colic, diarrhea, tachycardia, and congested mucous membranes after intramuscular administration of vaccines. The systemic signs are perhaps more common with certain vaccines but can be associated with any vaccine.[39,40] It is therefore inadvisable to give horses any injectable vaccine within 2 weeks before a show, performance event, sale, or domestic shipment or within 3 weeks before international shipment. It may also be beneficial to minimize environmental dust when vaccinating horses known to have allergic airway disease or hypersensitivity.[39]

If unacceptable reactions occur repeatedly, the need for continued annual or more frequent revaccination against individual antigens should be carefully reevaluated, taking into account risk of disease, balanced against the risk of an adverse reaction. Many of the horses that experience adverse reactions have received many doses of many vaccine antigens, repeated over many years. In this situation the vaccination protocol should be “pared down” so that only the most essential antigens are administered and the maximum possible interval between boosters is employed. For diseases such as rabies and tetanus for which resistance can reasonably be correlated with circulating antibody titer, one possible approach to define the maximum or optimal interval between booster doses would be to measure the antibody titer. Unfortunately, this approach is currently limited by paucity of laboratories that offer this type of testing on a routine basis, inexpensively, and with a short turnaround time. Introduction of commercially available ELISA testing for antibodies to the SeM protein of *S. equi* subsp. *equi* (Equine Biodiagnostics-Idexx, Lexington, Ky.) and neutralizing antibody testing for WNV (Cornell University, Colorado State University, the University of Florida, and the USDA Animal and Plant

Health Inspection Service [USDA/APHIS] National Veterinary Services Laboratory) in recent years has made it possible to refine vaccination protocols for these diseases in horses that experience adverse reactions to vaccination. In addition, testing for antibodies to other pathogens may be available through State Diagnostic Laboratories.

48.2.6 Safety of Vaccines in Broodmares

Consideration of vaccine safety in broodmares must take into account risks to the pregnancy and safety to the fetus. Potential adverse effects of vaccines on pregnancy are difficult to document, even when large numbers of mares are used, unless obvious problems occur. Because fetal organogenesis occurs early in gestation and this period is also characterized by substantial embryonic loss, even in normal mares, it is sound practice to avoid administering vaccines to mares during the first 60 days of gestation unless conditions of imminent risk prevail. Few vaccines carry specific label recommendations for use in pregnant mares, and few published data document the safety of equine vaccines during pregnancy. Of the available fully licensed vaccines, the two EHV-1 vaccines (Pneumabort-K+1b, Fort Dodge, and Prodigy, Intervet) marketed for use in pregnant mares as an aid to prevention of EHV-1 abortion, the vaccine marketed for prevention of type B botulism in foals (BotVax B, Neogen), and the Calvenza line of influenza and EHV vaccines (Boehringer Ingelhein, St. Joseph, Mo.) include directions for use in pregnant mares. In addition, the conditionally licensed vaccine for prevention of RV infection in foals (Equine Rotavirus Vaccine, Fort Dodge) is similarly labeled for use in pregnant mares. Although not specifically labeled for administration during pregnancy, widespread use in practice over many years has failed to document that any of the inactivated vaccines currently marketed for use in horses pose an unacceptable risk to pregnant mares. Therefore pregnant mares are routinely vaccinated with inactivated vaccines directed against tetanus, EEE, WEE, WNV, influenza, EHV-4, strangles, and, to a lesser extent, PHF, rabies, and VEE. Similarly, adverse impacts on pregnancy have not been documented for modified live intranasally administered strangles and influenza vaccines or the modified live parenterally administered EHV-1 vaccine (Rhinomune, Pfizer). In addition, safety of the recombinant WNV and influenza vaccines (Recombitek, Merial) should not be a significant concern because the modified live canarypox vector lacks the ability to infect mammalian cells. In contrast, modified live virus EVA and VEE vaccines and live anthrax spore vaccines should not be used in pregnant mares. Protection of mares against the potential abortigenic effects of EVA infection is therefore best accomplished by completing the primary immunization series before the mare enters the broodmare band and by administering subsequent boosters during the open period before rebreeding.[41]

1560
1561

The practice of booster vaccinating mares against multiple diseases to maximize colostral transfer of antibodies to the foal, and the fact that mares in broodmare bands are generally middle aged or older, result in the typical broodmare receiving multiple doses of many vaccine antigens and adjuvants during her lifetime. In addition to stimulating high levels of antibody against a range of antigens for the benefit of the foal, this practice may also predispose these mares to a higher rate of local and systemic adverse reactions, an issue that not only warrants further investigation but may force horse owners and veterinarians to carefully consider strategies for revaccination.

48.3 AVAILABLE VACCINES AND THE CONCEPT OF CORE AND NONCORE VACCINES

Fully licensed vaccines are now available in North America as aids to the prevention of tetanus, viral encephalomyelitis (EEE, WEE, VEE), WNV infection, influenza, EHV-1 and EHV-4 infection, strangles, rabies, EVA, PHF, and type B botulism. In addition, conditionally licensed vaccines are available to immunize horses against RV infection and equine protozoal myeloencephalitis (EPM). Tetanus and viral encephalomyelitis caused

by EEE, WEE, and WNV pose a threat to horses in all geographic areas and are therefore considered to be core diseases against which all horses in North America should be vaccinated. In addition, the public health consequences of infection and the 100% mortality rate warrant inclusion of rabies as a core disease for horses residing in or being transported to those many areas of North America where rabies is endemic in the wildlife population. The abortigenic potential of EHV-1 warrants inclusion of this disease in the core for all pregnant broodmares. Although influenza is not routinely included as a core disease, vaccination against this highly contagious respiratory tract infection is strongly recommended for all horses that are likely to be colocated with horses from other facilities during transportation or at sales, shows, trail rides, races, or other events. The remaining diseases for which vaccines are available are considered "noncore." Indications for use of vaccines against these diseases will be discussed in relevant sections that follow later in this chapter. Tables 48-2 and 48-3 provide general guidelines for use of the most frequently indicated equine vaccines in foals, weanlings, yearlings, and adult horses under various management conditions and in various geographic locations. Table 48-4 presents manufacturer recommendations for use of single-component equine immunizing agents and other biologicals licensed for use in horses.

48.4 VACCINATION RECOMMENDATIONS FOR SPECIFIC DISEASES

48.4.1 Tetanus

All horses are at risk for developing tetanus, an often-fatal disease caused by a potent neurotoxin elaborated by the anaerobic, spore-forming bacterium *Clostridium tetani*. Infection of tissues typically occurs via puncture wounds (particularly those involving the foot or muscle), open lacerations, surgical incisions, exposed tissues such as the umbilicus of foals and reproductive tract of the postpartum mare (especially in the event of trauma or retained placenta). *C. tetani* is present in the intestinal tract and feces of horses, other animals, and human beings, and spores are abundant as well as ubiquitous in soil. Spores of *C. tetani* survive in the environment for many years, resulting in an ever-present risk of exposure of horses and people on equine facilities. Tetanus is expensive to treat and has a high mortality rate; therefore all horses should be actively immunized using tetanus toxoid as part of the core vaccination program. Active immunization reduces the need to administer tetanus antitoxin, the use of which is associated with risk of inducing potentially fatal serum hepatitis.

Protection against tetanus is mediated by circulating antibodies; toxin binding inhibition (ToBi) antibody titers of >0.2 IU/mL are considered to be protective in the horse.[38,42] The many available vaccines are formalin inactivated, adjuvanted toxoids that are inexpensive, safe, and potent antigens that induce an excellent serologic response and solid, long-lasting immunity when administered according to manufacturer recommendations. Primary immunization involves administration of two doses of toxoid at 3- to 6-week intervals. Titers of specific antibody increase to protective levels within 14 days after administration of the second dose in the primary series and, in adult horses, persist at detectable levels for 12 months or longer, depending on the adjuvant system used in the vaccine.[38,42–44] A recent study documented substantial differences between currently licensed combination tetanus-encephalomyelitis vaccines with regard to the magnitude of the vaccine-induced tetanus-specific IgGb and IgG(T) antibody responses.[20] The vaccine containing a Carbopol adjuvant induced substantially higher antibody titers than those containing either saponin or squaline combined with surfactants.[20] Revaccination once annually is recommended.

Table 48-2 Guidelines for Vaccination of Foals, Weanlings and Yearlings Against Core and Non-Core Diseases

Disease/Vaccine*†	Foals And Weanlings (<12 Months of Age) of Mares Vaccinated in the Prepartum Period Against the Disease Indicated	Foals And Weanlings (<12 Months of Age) of Mares Not Vaccinated in the Prepartum Period	Yearlings	Comments
CORE DISEASES				
Tetanus (toxoid)	3-dose series: First dose at 4–6 months of age Second dose 4–6 weeks after the first dose Third dose at 3–5 months after the second dose (e.g.,10–12 months of age)	3-dose series: First dose at 1–4 months of age Second dose 4–6 weeks after the first dose Third dose 3–5 months after the second dose	Annual	
Eastern and Western equine encephalomyelitis (EEE, WEE)	3-dose series: First dose at 4–6 months of age Second dose 4–6 weeks after the first dose Third dose at 10–12 months of age, prior to onset of next vector season. *Foals in the Southeastern USA*: The primary vaccination series should be initiated with an additional dose at 3 months of age due to early seasonal vector presence.	3-dose series: First dose at 3–4 months of age Second dose 4–6 weeks after the first dose Third dose 3–5 months after the second dose, prior to onset of next vector season. *Foals in the Southeastern USA*: The primary vaccination series should be initiated at 3 months of age or earlier due to early seasonal vector presence.	Annual in spring, prior to onset of vector season	Month of birth and geographic location influence the risk of exposure to insect vectors at specific foal ages; therefore, scheduling of the primary immunization series may be amended by administration of EEE/WEE vaccines to foals at an earlier age if vectors are present.

West Nile virus (WNV)	**Inactivated vaccine:** 3-dose series: First dose at 4–6 months of age Second dose 4–6 weeks after the first dose Third dose at 10–12 months of age, prior to the onset of the next vector season	**Inactivated vaccine:** 3-dose series: First dose at 3–4 months of age Second dose 4 weeks after the first dose Third dose at 10–12 months of age, prior to the onset of the next vector season	Annual in spring, prior to onset of vector season	Month of birth and geographic location influence the risk of exposure to insect vectors at specific foal ages; therefore, scheduling of the primary immunization series may be amended by administration of WNV vaccines to foals at an earlier age if vectors are present.
	Recombinant canarypox-vectored vaccine: 3-dose series: First dose at 4–6 months of age Second dose 4–6 weeks after the first dose Third dose at 10–12 months of age, prior to the onset of the next vector season	**Recombinant canarypox-vectored vaccine:** 3-dose series: First dose at 3–4 months of age Second dose 4–6 weeks after the first dose Third dose at 10–12 months of age, prior to the onset of the next vector season		
	Flavivirus chimera vaccine: 2-dose series: First dose at 5–6 months of age Second dose at 10–12 months of age, prior to the onset of the next vector season *Foals in the Southeastern USA:* The primary vaccination series should be initiated at 3 months of age due to early seasonal vector presence.	**Flavivirus chimera vaccine:** 2-dose series: First dose at 5–6 months of age Second dose at 10–12 months of age prior to the onset of the next vector season. *Foals in the Southeastern USA*: The primary vaccination series should be initiated at 3 months of age due to early seasonal vector presence.		There is no data for the use of the Flavivirus chimera product in foals <5 months of age. If administered to foals <5 months of age, the recommended schedule for primary vaccination should be completed by administration of a dose of vaccine at 5 months of age or older.

Rabies	3-dose series: First dose at 6 months of age Second dose 4–6 weeks after the first dose Third dose at 10–12 months of age	3-dose series: First dose at 3–4 months of age Second dose 4–6 weeks after the first dose Third dose at 10–12 months of age	Annual	
NON-CORE (RISK-BASED) VACCINES				
Anthrax	Not applicable because vaccination of pregnant mares is not recommended.	No age specific guidelines are available for this vaccine. Manufacturer's recommendation is for primary series of 2 doses administered subcutaneously (in the neck) at a 2–3 week interval.	Annual, spring	Anthrax vaccination is rarely indicated—only in focal endemic areas. Antimicrobial drugs must **not** be given concurrently with this vaccine. Caution should be used during storage, handling and administration of this live bacterial product. Consult a physician immediately should accidental human exposure (via mucous membranes, conjunctiva, or broken skin) occur.
Botulism (type B toxoid)	3-dose series: First dose at 2–3 months of age Second dose 4 weeks after the first dose Third dose 4 weeks after the second dose	3-dose series: First dose at 1–3 months of age Second dose 4 weeks after the first dose Third dose 4 weeks after the second dose	Annual	Limited information suggests that maternal antibody does not interfere with vaccination; therefore, foals at high risk may be vaccinated as early as 2 weeks of age.

Equine herpesvirus (EHV)	**Inactivated EHV-1, EHV-1/4, or modified live EHV-1 vaccine:** 3-dose series: First dose at 4–6 months of age Second dose 4–6 weeks after the first dose Third dose 3–4 months after the second dose Revaccinate at 6-month intervals	**Inactivated EHV-1, EHV-1/4, or modified live EHV-1 vaccine:** 3-dose series: First dose at 4–6 months of age Second dose 4–6 weeks after first dose Third dose 3–4 months after the second dose Revaccinate at 6-month intervals	Semiannual (6-month intervals)	
Equine influenza	Inactivated vaccine: 3-dose series: First dose at 6 months of age Second dose 3–4 weeks after the first dose Third dose at 10–12 months of age Revaccinate at 6-month intervals	Inactivated vaccine: 3-dose series: First dose at 6 months of age Second dose 3–4 weeks after the first dose Third dose at 10–12 months of age Revaccinate at 6-month intervals	Semiannual (6-month intervals)	An increased risk of disease may warrant vaccination of younger foals. Because potentially interfering maternal anti-influenza antibody is likely to be present, a complete primary vaccination should be given after 6 months of age.
	Modified live intranasal vaccine: 2-dose series administered intranasally: First dose at 6–7 months of age Second dose at 11–12 months of age Revaccinate at 6-month intervals	Modified live intranasal vaccine: 2-dose series administered intranasally: First dose at 6–7 months of age Second dose at 11–12 months of age Revaccinate at 6-month intervals	Annual	The modified live intranasal vaccine is licensed for administration to horses 11 months of age or older. If the vaccine is given before 11 months of age, a second dose should be administered at 11 months or older.
	Canarypox-vectored recombinant vaccine: 3-dose series: First dose at 5 months of age Second dose 5 weeks after the first dose Third dose at 10–12 months of age Revaccinate at 12-month intervals	Canarypox-vectored recombinant vaccine: 3-dose series: First dose at 5 months of age Second dose 5 weeks after the first dose Third dose at 10–12 months of age Revaccinate at 12-month intervals		

Equine viral arteritis (EVA)	*Colt (male) foals*: Single dose at 6–12 months of age (see comments)	*Colt (male) foals*: Single dose at 6–12 months of age (see comments)	Annual for colts intended for use as breeding stallions	*Prior to initial vaccination, colt (male) foals should undergo serologic testing* and be confirmed negative for antibodies to EAV. Testing should be performed shortly prior to, or preferably at, the time of vaccination. Maternally-derived anti-EAV colostral antibodies can persist in the foal for up to 6 months; therefore, testing and vaccination should **not** be performed prior to 6 months of age.
Potomac horse fever (PHF)	3-dose series: First dose at 5–6 months of age Second dose 3–4 weeks after the first dose Third dose at 10–12 months of age	3-dose series: First dose at 5–6 months of age Second dose 3–4 weeks after the first dose Third dose at 10–12 months of age	Semiannual to annual	If risk warrants, vaccine may be administered to younger foals, in which case subsequent doses should be administered at 4-week intervals until 6 months of age.
Rotovirus	Not recommended in foals	Not recommended in foals	NA	
Strangles	**Inactivated M-protein subunit vaccines:** 3-dose series: First dose at 4–6 months of age Second dose 4–6 weeks after the first dose Third dose 4–6 weeks after the second dose	**Inactivated M-protein subunit vaccines:** 3-dose series: First dose at 4–6 months of age Second dose 4–6 weeks after the first dose Third dose 4–6 weeks after the second dose	Semiannual	Vaccination is **not** recommended as a strategy in outbreak mitigation.

	Modified live intranasal vaccine: 3-dose series administered intranasally: First dose at 6–9 months of age Second dose 3–4 weeks after the first dose Third dose at 11–12 months of age	**Modified live intranasal vaccine:** 3-dose series administered intranasally: First dose at 6–9 months of age Second dose 3–4 weeks after the first dose Third dose at 11–12 months of age	If warranted by risk, the modified live vaccine (MLV) may be safely administered to foals as young as 6 weeks of age. However, vaccine efficacy in this age group has not been determined. If the MLV product is administered to foals less than 6 months of age, a third dose of vaccine should then be administered 2- 4 weeks prior to weaning.

Modified, with permission, from recommendations developed by the AAEP Infectious Disease Committee and posted on the AAEP website (aaep.org) in January 2008.

* Core vaccines protect against diseases that are endemic to a region, are virulent or highly contagious, pose a risk of severe or fatal disease, have potential public health significance, and/or are required by law. Core vaccines have clearly demonstrable efficacy, and have a sufficiently high level of patient benefit and low level of risk to justify their use in all equids in North America.

† Non-core (risk-based) vaccines are selected for use based on assessment of risk performed by, or in consultation with, a licensed veterinarian. Use of non-core vaccines will vary between individuals, populations, and/or geographic regions.

Table 48-3 Guidelines for Vaccination of Adult Horses Against Core and Non-Core Diseases

Disease/Vaccine*†	Broodmares	Other Adult Horses (>1 Year of Age) Previously Vaccinated Against the Disease Indicated	Other Adult Horses (>1 Year of Age) *Not Previously Vaccinated* Against the Disease Indicated or Lacking a Vaccination History	Comments
CORE DISEASES				
Tetanus (toxoid)	*Previously vaccinated:* Annual, 4–6 weeks prepartum *Not previously vaccinated or vaccination history unknown:* 2-dose series: Second dose 4–6 weeks after the first dose Revaccinate 4–6 weeks prepartum	Annual	2-dose series: Second dose 4–6 weeks after the first dose	Booster at time of penetrating injury or surgery if last dose was administered more than 6 months previously
Eastern and Western equine encephalomyelitis (EEE, WEE)	*Previously vaccinated:* Annual, 4–6 weeks prepartum *Not previously vaccinated or vaccination history unknown:* 2-dose series: Second dose 4 weeks after the first dose Revaccinate 4–6 weeks prepartum	Annual in spring, prior to onset of vector season	2-dose series: Second dose 4 weeks after the first dose; revaccinate prior to onset of the next vector season.	Consider 6-month revaccination interval for horses residing in endemic areas with a? prolonged vector season or immunocompromised horses.

West Nile virus (WNV)	*Previously vaccinated:* Annual, 4–6 weeks prepartum *Not previously vaccinated or vaccination history unknown:* It is preferable to vaccinate naïve mares when open. In areas of high risk, initiate primary series as described for adult horses that have not previously been vaccinated.	Annual in spring, prior to onset of vector season	**Inactivated vaccine:** 2-dose series: Second dose: 4–6 weeks after the first dose; revaccinate prior to onset of the next vector season **Recombinant canarypox-vectored vaccine:** 2-dose series: Second dose: 4–6 weeks after the first dose; revaccinate prior to onset of the next vector season **Flavivirus chimera vaccine:** One dose; revaccinate prior to onset of the next vector season.	When using the inactivated or the recombinant product, consider a 6-?month revaccination interval for: Horses residing in endemic areas with a prolonged vector season. Juvenile horses (<5 years of age) Geriatric horses (>15 years of age) Immunocompromised horses For naïve horses being imported into an endemic area during the vector season, the?preferred approach is to complete the primary vaccination series prior to importation. If this approach is not feasible, protect them from being bitten by mosquitoes if possible, and vaccinate them with one of the vaccines (Flavivirus chimera or canarypox-vectored) that have the most rapid onset of immunity.
Rabies	Annual, prior to breeding OR 4–6 weeks prepartum	Annual	One dose; annual revaccination	Because booster vaccination induces persistently elevated levels of antirabies antibody, this vaccine may be given postfoaling, but prior to breeding, in order to reduce the number of vaccines given to mares prepartum.
NON-CORE (RISK-BASED) VACCINES				

Anthrax	Not recommended for use during gestation.	Annual	2-dose series: Second dose 3–4 weeks after the first?dose; annual revaccination.	Use only in endemic areas or in the face of an outbreak. Antimicrobial drugs must ***not*** be given concurrent with this vaccine. Administer subcutaneously in the neck. Use caution during storage, handling and administration. Consult a physician immediately if human exposure to anthrax vaccine occurs by accidental injection, ingestion, or otherwise through the conjunctiva or broken skin.
Botulism	*Previously vaccinated:* Annual, 4–6 weeks prepartum *Not previously vaccinated or vaccination history unknown:* 3-dose series: First dose during eighth month of gestation Second dose 4 weeks after the first dose Third dose 4 weeks after the second dose	Annual	3-dose series: Second dose 4 weeks after the first dose Third dose 4 weeks after the second dose	
Equine herpesvirus (EHV)	3-dose series with product labeled for prevention against EHV abortion. Administer during the fifth, seventh, and ninth months of gestation.	Annual (see comments)	3-dose series: Second dose: 4–6 weeks after the first dose Third dose: 4–6 weeks after the second dose	Consider 6-month revaccination interval for: Horses <5 years of age Horses on breeding farms in contact with pregnant mares Performance or show horses at high risk

Equine influenza	*Previously vaccinated:* **Inactivated vaccines:** Semiannual with one dose administered 4–6 weeks prepartum **Canarypox-vectored vaccine:** Semiannual with one dose administered 4–6 weeks prepartum *Not previously vaccinated or vaccination history unknown:* **Inactivated vaccine:** 3-dose series: Second dose 4–6 weeks after the first dose Third dose 4–6 weeks prepartum **Canarypox-vectored vaccine:** 2-dose series: Second dose 4–6 weeks after first dose but no later than 4 weeks prepartum	Semiannual for horses with ongoing risk of exposure Annual for horses at low risk for exposure	**Modified live intranasal vaccine:** One dose administered IN. Revaccinate semiannually to annually. **Inactivated vaccines:** 3-dose series: Second dose: 4–6 weeks after the first dose Third dose: 3–6 months after the second dose Revaccinate semiannually to annually. **Canarypox-vectored recombinant:** 2-dose series: Second dose 4–6 weeks after the first dose. Revaccinate semiannually.	The MLV intranasal vaccine can be used to protect pregnant mares against influenza, but its use for the prepartum booster is not recommended because it does not reliably stimulate high levels of circulating antibody.
Equine viral arteritis (EVA)	Not recommended unless risk of exposure is high	Annual *Stallions and teasers*: Vaccinate 3–4 weeks before the start of the breeding season *Mares:* Vaccinate when open	Single dose (see comments)	Prior to initial vaccination, intact males and any horses potentially intended for export should undergo serologic testing and be confirmed negative for antibodies to EAV. Samples for testing should be collected shortly prior to, or preferably at, the time of vaccination.

Potomac horse fever (PHF)	*Previously vaccinated:* Semiannual with one dose administered 4–6 weeks prepartum *Not previously vaccinated or vaccination history unknown:* 2-dose series: First dose 8–10 weeks prepartum Second dose 4–6 weeks prepartum	Semiannual to annual	2-dose series: Second dose: 3–4 weeks after the first?dose Revaccinate semiannually to annually.	A revaccination interval of 3–4 months may be considered in endemic areas when disease risk is high; however, strategic revaccination to maximize immunity prior to expected peak challenge in the summer and fall is the preferred approach.
Rotovirus	3-dose series: First dose at 8 months gestation Second dose 4 weeks after the first dose Third dose 4 weeks after the second dose	NA	NA	Check serum concentrations of immunoglobulins in the foal to verify adequate passive transfer
Strangles	*Previously vaccinated:* **Inactivated M-protein subunit vaccines:** Semiannual with one dose given 4–6 weeks prepartum *Not previously vaccinated or vaccination history unknown:* **Inactivated M-protein subunit vaccines:** 3-dose series: Second dose 2–4 weeks after the first dose Third dose 4–6 weeks prepartum	Semiannual to annual	**Inactivated M-protein subunit vaccines:** 2 to 3-dose series: Second dose 2–4 weeks after the first dose Third dose (when recommended by manufacturer) 2–4 weeks after the second dose Revaccinate semiannually. **Modified live intranasal vaccine:** 2-dose series administered IN: Second dose 3–4 weeks after the first dose Revaccinate semiannually to annually.	Vaccination is not recommended as a strategy in outbreak mitigation.

Modified, with permission, from recommendations developed by the AAEP Infectious Disease Committee and posted on the AAEP website (aaep.org) in January 2008.

* Core vaccines protect against diseases that are endemic to a region, are virulent or highly contagious, pose a risk of severe or fatal disease, have potential public health significance, and/or are required by law. Core vaccines have clearly demonstrable efficacy, and have a sufficiently high level of patient benefit and low level of risk to justify their use in all equids in North America.

† Non-core (risk-based) vaccines are selected for use based on assessment of risk performed by, or in consultation with, a licensed veterinarian. Use of non-core vaccines will vary between individuals, populations, and/or geographic regions.

Table 48-4 Manufacturers' Recommendations for Use of Single Component Equine Immunizing Agents and Biologics

Disease	Etiologic Agent	Type of Product	Available Products	Manufacturer	Dose
Anthrax	*Bacillus anthracis*	Nonencapsulated live bacterial spores	Anthrax Spore Vaccine	Colorado Serum Co.	l mL
Botulism (shaker foal syndrome)	*Clostridium botulinum* type B toxin	Toxoid	BotVax-B	Neogen Corporation	2 mL
*Escherichia coli*septicemia	*E. coli*	*E. coli* antibody, equine origin	Equine Coli Endotox	Novartis (Food Animal)	10 mL
		*E. coli*antiserum, equine origin	E. Colicin-E	Agri Labs	10 mL
Endotoxemia	*Salmonella typhimurium*	Inactivated; bacterin toxoid	Endovac-Equi	Immvac	1 mL
	Endotoxin produced by gram-negative bacteria	*Salmonella typhimurium* antiserum, equine origin	Endoserum	Immvac	1.5 mL/kg (0.7 mL/lb)
Equine encephalomyelitis	Bivalent vaccines: WEE, EEE	Inactivated; chicken tissue culture origin	Encevac	Intervet	1 mL
		Inactivated; cell culture origin	Encephalomyelitis vaccine, eastern and western	Colorado Serum Co.; Professional Biological	1 mL
Equine viral arteritis	Equine arteritis virus	Modified live; equine cell line origin	Arvac	Fort Dodge Animal Health	1 mL
Equine influenza	Equine influenza A equine 2	Modified live (cold adapted)	FluAvert I.N.	Intervet	Entire contents of vial after reconstitution
		Recombinant, canarypox-vectored	Recombitek Equine Influenza Virus	Merial	2 mL
		Inactivated; canine kidney call line origin	Fluvac Innovator	Fort Dodge Animal Health	1 mL
		Inactivated; cell line origin	Flumune A2 KY98	Pfizer Animal Health	1 mL
		Inactivated; cell line origin	Calvenza-03 EIV	Boehringer Ingelheim	2 mL

Route	Age for Primary Series	Regimen for Primary Series	Regimen for Revaccination	Comments*
SC		Two doses 2–3 weeks apart	Annual	Vaccinate 4 weeks before possible exposure. Light to moderate swelling may occur at the injection site. Do not administer antibiotics within 1 week of vaccination.
IM		Three doses at least 4 weeks apart	Annual	In pregnant mares, administer booster 4 weeks before parturition. Protects only against botulism caused by *C. botulinum* type B.
PO	Within 12 hours of birth			Colostrum should be fed to each foal.
PO	Within 12 hours of birth			Colostrum should be fed to each foal.
IM	6 months or older	Two doses 2–3 weeks apart	Annual	Indicated for prevention of endotoxin-mediated disease caused by *S. typhimurium* and *E. coli*. Label includes multiple precautions—read thoroughly.
IV				When treating failure of passive transfer in foals, administer 500 mL to a 70-lb foal.
IM		Two doses 3–4 weeks apart	Annual or at any time epidemic conditions exist or are reported and exposure is imminent or likely.	Time primary series and boosters to precede mosquito season.
IM		Two doses 3 weeks apart		
IM	6 weeks or older	One dose	Annual	Prior authorization by a state veterinarian is recommended, and a permit may be necessary (regulations vary from state to state). Vaccinate stallions at least 3 weeks before breeding season. Vaccinate mares as maidens or while open at least 3 weeks before breeding. Pregnant mares should not be vaccinated during the last 2 months of gestation. Vaccinated horses may be ineligible for export because of seroconversion.

IN	11 months or older	One dose	Semiannual. Horses at high risk may benefit from revaccination every 3 months.	Contains Kentucky/91 (A_2) strain. Horses vaccinated before 11 months of age should be given a dose of vaccine at age 11 months. This vaccine is NOT intended for IM or SC administration.	
IM	5 months or older	Two doses, 5 weeks apart	Annual	Contains Kentucky/94 (A_2) and Newmarket/2/93 (A_2) strains.	
IM		Two doses 3–4 weeks apart	Annual	Contains Kentucky/97 (A_2) strain.	
IM		Two doses 2–3 weeks apart	Annual or whenever epizootic conditions exist and exposure is likely.	Contains Kentucky/98 (A_2) strain.	
IM for first two doses; IM or IN for subsequent doses	6 months or older	Two doses 3–4 weeks apart	Annual or prior to anticipated exposure	Contains Ohio/2003 (A_2), Newmarket 2/93 (A_2), and Kentucky/95 (A_2) strains. The first and second doses must be administered by the IM route; the third and subsequent booster doses may be administered by either IM or IV routes. Labeled for use in pregnant mares.	
Disease	**Etiologic Agent**	**Type of Product**	**Available Products**	**Manufacturer**	**Dose**
Rotaviral diarrhea	Rotavirus	Inactivated	Equine rotavirus vaccine	Fort Dodge Laboratories	1 mL
Equine monocytic ehrlichiosis(Potomac horse?fever)	*Neorickettria risticii*	Inactivated	PHF-Gard	Pfizer Animal Health	1 mL
		Inactivated	Equine Potomavac	Merial	1 mL
		Inactivated	PotomacGuard	Fort Dodge Animal?Health	1 mL
		Inactivated	Equovum PHF	Boehringer Ingelheim	1 mL
		Inactivated	Mystique	Intervet	1 mL
Rabies	Rabies virus	Inactivated; cell line origin	Imrab 3	Merial	2 mL
		Inactivated; cell line orign	Imrab Large Animal	Merial	2 mL
		Inactivated; cell line origin	Rabvac 3	Fort Dodge Animal Health	2 mL

		Inactivated; cell line origin	Rabvac 3TF	Fort Dodge Animal?Health	2 mL
Rhinopneumonitis	Equine herpesvirus type 1 (EHV-1)	Inactivated	Pneumabort-K+1b	Fort Dodge Laboratories	2 mL
		Inactivated; tissue culture origin	Prodigy	Intervet	2 mL
		Modified live; equine cell line orign	Rhinomune	Pfizer	1 mL
	EHV-1 and EHV-4	Inactivated bivalent;tissue culture origin	Prestige	Intervet	1 mL
		Inactivated bivalent	Equivac Innovator EHV-1/4	Fort Dodge Animal?Health	1 mL
Strangles	*Streptococcus equi* subsp. *equi*	Modified live	Pinnacle I.N.	Fort Dodge Animal?Health	2.5 mL
		Inactivated;bacterial M-?protein extract	Strepguard	Intervet	1 mL
		Inactivated;bacterial M-?protein extract	StrepVax II	Boehringer Ingelheim	1 mL
Route	Age for Primary Series	Regimen for Primary Series	Regimen for Revaccination	Comments*	
IM	Adult broodmares	Three doses, 4 weeks apart during the eighth, ninth, and tenth months of gestation.	Annually, three doses during the eighth, ninth, and tenth months of gestation.	Contains the G3 (H2) serotype of equine rotavirus. Product is conditionally licensed by the USDA, while additional efficacy and potency data are being developed, for vaccination of pregnant mares to promote passive transfer to foals of antibodies against equine rotavirus.	
IM	1 year or older	Two doses 2–3 weeks?apart	Annual		
IM	3 months or older	Two doses 3–4 weeks?apart	Annual		
IM		Two doses 3–4 weeks?apart	Annual		
IM	3 months or older	Two doses 3–4 weeks?apart	Annual		
IM	3 months or older	Two doses 3–4 weeks?apart	Annual, or when epidemic conditions exist or are reported and exposure is imminent.		

	IM or SC	3 months or older	One dose	Annual	Effectiveness of a single dose of rabies vaccine in the primary series for foals has recently been questioned (see text).
	IM	3 months or older	One dose	Annual	
	IM	3 months or older	One dose	Annual	
	IM	3 months or older	One dose	Annual	
	IM		Two doses 3–4 weeks?apart	*Pregnant mares for abortion prevention*: Repeat doses annually during fifth, seventh, and ninth months of gestation; *Young horses:* 6 months after primary series and annually thereafter	Vaccinate open and maiden mares at the same time as pregnant mares. For mares beyond the fifth month of gestation when vaccination is initiated, vaccinate on presentation and every 2 months thereafter until foaling.
	IM	6 months or older	Three doses 4–6 weeks?apart	*Pregnant mares for abortion prevention:* annually during the fifth, seventh, and ninth months of gestation. *Respiratory disease prevention:* Annually or at any time epidemic conditions exist or are reported and exposure is imminent.	Maiden and barren mares housed or pastured with pregnant mares should be vaccinated on the same schedule. Booster

IM	3 months or older	Two doses 3–4 weeks?apart	3-month intervals	Vaccine is approved for use in pregnant mares, but no label claim is made for prevention of EHV-1 abortion. Vaccinate pregnant mares after the second month of gestation. Foals vaccinated before 3 months of age should receive a 2-dose series after reaching 3 months of age.	
IM		Two doses 4–6 weeks apart	Annual or any time epidemic conditions exist or are reported and exposure is imminent.	Approved for use in pregnant mares, but no label claim is made for prevention of EHV-1 abortion.	
IM		Two doses 3–4 weeks?apart	Annual		
IN		Two doses at 2–3 week?intervals	Annual	For intranasal use only. Do not administer parenterally by injection.	
IM		Two doses 3–4 weeks?apart	Annual or before expected exposure	Foals vaccinated when less than 3 months of age should receive an additional dose at 6 months.	
IM	3 months or older	Three doses at 3-? week intervals	Annual or before expected exposure

Information on combination vaccines is available in *Compendium of Veterinary Products*, ed 9, Port Huron, Mich, 2006, North American Compendiums.

Note: The recommendations contained in this table were obtained from package inserts or from the *Compendium of Veterinary Products*, ed 9. In those instances in which research or extensive field experience indicate that increased efficacy can be achieved through use of alternative vaccination protocols, recommendations contained in Table 48-4 may differ from those in Tables 48-2 and 48-3.

* Avoid administering immediately before an athletic event or show, because transient, usually self-limiting febrile responses may occur after vaccination.

1571

1572

No published challenge studies are available to document the speed of onset or duration of protection induced by tetanus toxoid preparations currently licensed in North America; conclusions regarding their efficacy are therefore based on the serologic response obtained in horses and laboratory animals and on field experience. However, a challenge study conducted in Europe more than 40 years ago found that horses were resistant to challenge 8 days after receiving a single injection of tetanus toxoid, before antibody could be detected in their serum.[45] A second study demonstrated that a series of three doses of tetanus toxoid induced protection lasting for at least 8 years, and perhaps for life, even when antibodies could no longer be detected.[42] In contrast, tetanus has been documented in vaccinated horses in North America,[46] although survival was strongly associated with previous vaccination. Thus it would not be prudent to recommend extension of the annual interval for revaccination with tetanus toxoid, pending publication of data documenting duration of immunity

(DOI). Vaccinated horses that sustain a wound or undergo surgery more than 6 months after receiving their previous tetanus booster should be revaccinated with tetanus toxoid immediately at the time of injury or surgery.

Annual revaccination of pregnant mares should be completed 4 to 8 weeks before foaling to protect the mare if she sustains foaling-induced trauma or retained placenta and to enhance concentrations of specific immunoglobulins in colostrum. Colostrum-derived antibodies significantly interfere with the immune response of foals vaccinated with tetanus toxoid until they are approximately 6 months of age.[23,44]

Primary vaccination of foals that have received appropriate transfer of colostral antibodies from a vaccinated mare should include three doses of tetanus toxoid beginning at age 6 months or older. The interval between the first two doses of vaccine should be approximately 4 weeks, and the interval between the second and third doses should be 8 to 16 weeks. The three-dose primary series is recommended for foals because a high proportion of foals fail to seroconvert in response to two doses of tetanus toxoid, regardless of whether maternal antibodies are detectable at administration of the first dose.[23,44] For foals born to nonimmune mares, this initial three-dose series can start at 1 to 4 months of age.

Tetanus antitoxin is produced by hyperimmunization of donor horses with tetanus toxoid. Administration of one vial of antitoxin (1500 IU) to unvaccinated horses induces immediate passive protection that lasts not more than 3 weeks.[44] More prolonged protection may be accomplished with higher doses. In addition to the use of high doses of tetanus antitoxin to treat tetanus, indications frequently cited include administration to newborn foals born to unvaccinated mares and to unvaccinated horses that sustain an injury. In these cases the concurrent administration of tetanus antitoxin and tetanus toxoid at different sites using separate syringes has been advocated, followed by administration of additional doses of toxoid at 4- to 6-week intervals to complete the primary series.[47] Because a small but significant number of horses experience serum sickness and fatal hepatic failure (serum hepatitis) several weeks after receiving tetanus antitoxin,[48,49] a preferred approach to the unvaccinated horse that sustains a puncture or deep laceration is to thoroughly clean and debride the wound, initiate active immunization by administering tetanus toxoid, and institute a course of antimicrobial treatment with penicillin or alternate antimicrobial that is active against *C. tetani*.

48.4.2 Equine Encephalomyelitis (Sleeping Sickness)

The equine encephalomyelitis viruses (EEE, WEE, and VEE) belong to the Alphavirus genus of the family Togaviridae. They are transmitted by mosquitoes, and infrequently by other bloodsucking insects, to horses from wild birds or rodents, which serve as natural reservoirs for these viruses. Risk of exposure and geographic distribution of the encephalomyelitis viruses vary by season and from year to year with changes in distribution of insect vectors and wildlife reservoirs. The distribution of EEE has historically been restricted to the eastern, southeastern, and some southern states with recent northward encroachment. WEE has caused minimal disease in horses in North America during the last two decades; however, the virus continues to be detected in mosquitoes and birds throughout the Western states. In the past, outbreaks of WEE have been recorded in the western and midwestern states, with sporadic cases in the Northeast and Southeast United States. Because EEE, WEE, or both are endemic in most areas of North America, vaccination against these diseases should be part of the core vaccination program for all horses. VEE is a reportable foreign animal disease. Epidemics of VEE occur when the virus undergoes genetic change and develops greater virulence for avian and mammalian hosts. These viral variants are able to multiply to high levels in the horse, and then the horse becomes a reservoir for infection in these outbreaks. VEE occurs in South and Central America but has not been diagnosed in the

1572
1573

United States or Mexico for many years; therefore routine vaccination of horses in these regions against VEE is not recommended at this time, unless transportation to endemic areas is planned.

Available vaccines are formalin inactivated, adjuvanted, bivalent whole-virus products containing EEE and WEE (Encevac with Havlogen, Intervet; Encephaloid Innovator, Fort Dodge; Cephalovac EW, Boehringer Ingelheim), or trivalent products that also contain VEE (Cephalovac VEW, Boehringer Ingelheim). Veterinarians and horse owners often use combination products containing other antigens, such as tetanus, influenza, WNV, or EHV for primary or booster immunization of horses against encephalomyelitis viruses. Although correlates for protection against EEE, WEE, and VEE are not well established, circulating antibodies are assumed to be important because infection is acquired by vascular injection (mosquito bites) and current inactivated vaccines appear to have good efficacy.[50,51] A study evaluating the serologic response of horses to commercial encephalomyelitis-tetanus combination vaccines showed that the EEE neutralizing antibody responses to Encevac T (Intervet, Carbopol adjuvant) and Equiloid (Fort Dodge, squaline and surfactant adjuvant) were of greater magnitude and persistence than responses to Cephalovac EWT (Boehringer Ingelheim, saponin adjuvant).[20] However, no comparative randomized challenge studies have been performed using these vaccines to document whether differences in serologic responses equate to differences in efficacy. Early testing of bivalent (EEE/WEE) vaccines was performed by intracranial challenge with either EEE or WEE; the formalin inactivated preparations demonstrated 100% protection.

Primary immunization of unvaccinated adult horses is accomplished by administering two doses of inactivated vaccine 3 to 6 weeks apart. In areas where EEE is not a threat and mosquito vectors are active for less than 6 months of the year, annual revaccination in the spring, before the peak insect vector season, is recommended. In areas such as the Gulf States where EEE is endemic and mosquitoes are active virtually year-round, many veterinarians prefer to revaccinate horses semiannually to ensure more uniform protection throughout the year. Inactivated encephalomyelitis vaccines are considered to be safe for use during pregnancy; therefore booster vaccination of pregnant mares 4 to 8 weeks before foaling is routinely recommended to enhance colostral concentrations of specific immunoglobulins. Neutralizing antibodies to WEE and EEE are transferred passively to foals through colostrum and decline with an estimated half-life of 33 and 20 days, respectively. MDAs appear to confer protection and are detectable in the serum of many foals from vaccinated mares for at least 3 months and up to 7 months, depending on the postnursing titer.[34,52–54]

1573

1574

Several studies have shown that MDAs exert a profound inhibitory effect on the ability of foals to mount serologic responses to inactivated bivalent WEE/EEE vaccines, which likely accounts for some of the reported cases of vaccine failure and resultant clinical EEE in vaccinated horses, particularly those less than 2 years of age.[30,34,35,52,53] Studies have shown that 3-month-old foals born to immune mares consistently failed to mount a serologic response to two doses of inactivated bivalent WEE/EEE vaccine and the majority had not responded even after administration of a third dose.[35,37] Whereas many 6-month-old foals failed to seroconvert after administration of two doses of vaccine, most responded after administration of a third dose.[35] Based on these data, inclusion of a third dose in the primary series, 8 to 16 weeks after administration of the second dose, is strongly recommended for primary immunization of foals and yearlings.

WEE has a lower mortality rate than EEE, and prevalence of WEE in many western states is sufficiently low that the risk of foals acquiring infection during their first year of life is also low. Therefore primary vaccination of foals of vaccinated mares in areas where mosquitoes die off in the winter and the risk of infection is low is best completed when foals are 5 to 6 months of age or older in order to minimize the potential for MDA interference. Because foals born in the late spring and summer months are still less than 6 months of age by the time the mosquito season comes to an end in many regions, primary vaccination of these foals can be delayed

until the spring of the yearling year. In contrast, EEE is a highly fatal disease that poses a significant risk to foals during their first year of life, particularly in the Gulf States, where competent vectors are present year-round.[30,53,55] Therefore most veterinarians in these regions recommend commencing primary vaccination of foals at 3 to 4 months of age using a three-dose primary series followed by a fourth dose before the onset of the next mosquito season and semiannual boosters thereafter, to maximize the chances of overcoming the inhibitory effects of MDAs and inducing protection.[53]

48.4.3 West Nile Virus

In the few years since WNV infection was first diagnosed in horses in the northeastern United States in 1999, it has spread across the entire North American continent and is now considered to be endemic in all mainland areas of North America and Mexico, where it has become an important consideration in the differential diagnosis of horses with signs of neurologic disease. As of June 2007 the disease had been confirmed in almost 25,000 horses in the United States, approximately 35% of which had died or been euthanized. Approximately 40% of horses that survive acute illness caused by WNV exhibit residual effects, such as gait and behavioral abnormalities, 6 months postdiagnosis.[56]

WNV, a member of the family Flaviviridae, is transmitted by mosquitoes and infrequently by other bloodsucking insects to horses, human beings, and a number of other mammals from avian hosts, which serve as natural reservoirs for these viruses. Horses and humans are considered to be “dead-end” hosts of the WNV and therefore do not contribute to the transmission cycle. The virus is not directly contagious from horse to horse or from horse to human. Similarly, indirect transmission via mosquitoes from infected horses is highly unlikely because horses do not experience a significant level of viremia.[57] Risk of infection and death appears to increase with increasing age; however, the disease has been confirmed in foals as young as 3 weeks of age. Although cases have been seen virtually year-round in the southeastern United States, the risk of acquiring infection is highest during those months in which mosquito activity peaks, typically July, August, September, and October in most areas of North America. WNV infection is a core disease against which all horses residing in the continental United States and Canada should be vaccinated.

As of June 2007, three fully licensed vaccines (West Nile—Innovator, Fort Dodge Animal Health; Recombitek, Merial; and PreveNile, Intervet) were marketed for use in horses in North America. West Nile—Innovator is an inactivated whole virus vaccine that contains a metabolizable oil adjuvant.[9] This vaccine is available as either a monovalent (single component) or as a multivalent vaccine containing other encephalitis virus antigens (EEE and WEE). Recombitek is a Carbopol-adjuvanted canarypox-vectored recombinant modified live vaccine,[11,12,17] and PreveNile is a nonadjuvanted chimeric yellow fever—vectored vaccine.[15,58] A fourth vaccine, a plasmid DNA vaccine with a metabolizable oil adjuvant (Fort Dodge Animal Health) was licensed in 2005 but had not been marketed as of June 2007.[13] All four vaccines have met USDA requirements for safety in tests, each involving more than 640 horses.

Needle and mosquito challenge models have shown that West Nile—Innovator, Recombitek, and the plasmid DNA vaccine all significantly reduce the magnitude of viremia in experimentally infected, vaccinated horses compared with unvaccinated control horses for as long as 12 months after primary vaccination with two doses of vaccine.[9,11,13,59] Although viremia was reliably induced in unvaccinated control horses in these challenge models, clinical disease was not. Therefore West Nile—Innovator and Recombitek are labeled as aids to the prevention of viremia caused by WNV infection. In contrast, an intrathecal challenge model that reliably induced severe clinical disease was used to test the efficacy of PreveNile in studies for licensure.[15,16] In this

model a single dose of PreveNile prevented clinical disease as well as viremia in 4- to 6-month-old horses challenged 1 year after vaccination; therefore PreveNile is labeled for protection against viremia and as an aid in the prevention of disease and encephalitis caused by WNV.[15,16] Subsequently, Recombitek was shown to induce a high level of clinical protection when tested using this rigorous intrathecal challenge model in a placebo-controlled study in which horses were challenged 14 days after completion of a two-dose vaccination series.[17] The comparative efficacy of West Nile—Innovator, Recombitek, and PreveNile has now been tested in a randomized, blinded, placebo-controlled intrathecal challenge study in which groups of five or six horses ≥6 months of age were challenged intrathecally 28 days after completion of the two-dose (West Nile—Innovator and Recombitek) or one-dose (PreveNile) primary vaccination series.[59] In this study, all six unvaccinated control horses developed grave neurologic signs postchallenge, whereas all vaccinated horses survived and none developed detectable viremia. Clinical disease was prevented in 100% of PreveNile-vaccinated horses, 80% of Recombitek-vaccinated horses, and 33% of Innovator-vaccinated horses. These findings support the results of field studies that provide clear evidence that, when used according to manufacturer recommendations, both West Nile—Innovator and Recombitek reduce the risk of disease and death after natural challenge, although clinical disease may not be fully prevented.[60–62]

Directions for primary immunization using West Nile—Innovator and Recombitek include administration of two doses of vaccine 3 to 6 weeks apart (consult the specific label). Optimal protection cannot be expected until 2 weeks after administration of the second dose, although Recombitek has been shown to induce significant protection as early as 26 days after administration of the first dose when tested in both the mosquito challenge and intrathecal challenge models.[12,17] Primary immunization with PreveNile requires one dose. A challenge study in yearlings showed that 83% (five of six) were protected when challenged intrathecally 10 days after vaccination with one dose, indicating that onset of immunity is rapid (Vaala W, personal communication, 2007). Rapid onset of immunity is an important feature when faced with the challenge of protecting naive horses that are being introduced into an endemic area, as is the case when horses from Europe and other nonendemic countries are imported into North America.

1574

1575

Vaccine manufacturers recommend revaccination of previously vaccinated horses on an annual basis, or more frequently when local conditions are conducive to a prolonged period of potential exposure to infected mosquito vectors. Annual revaccination is best completed in the spring (late February through early April), before the onset of the insect vector season. In areas such as the southeastern states where the mosquito season is prolonged, revaccination twice annually, once in the spring and again in the late summer or early fall (late July through early September) has been advocated in the past to maximize protection, although the rationale for semiannual vaccination against WNV has not been tested in controlled studies.

None of the licensed vaccines currently marketed in the United States carry label recommendations for administration to pregnant mares; therefore it is recommended that mares be vaccinated before breeding whenever possible. It is well recognized, however, that pregnant mares are at risk for acquiring infection from infected mosquitoes. Consequently it has become accepted practice by many veterinarians to administer vaccines to pregnant mares on the reasonable assumption that the risk of adverse consequences of WNV infection far exceeds the reported adverse effects of use of vaccines in pregnant mares. Thousands of doses of West Nile—Innovator vaccine have been administered safely to pregnant mares, and a published study failed to document vaccine-associated adverse effects in a large population of pregnant mares.[63] Although the Recombitek vaccine is a live vectored vaccine, the canarypox vector is incapable of replication in mammals and does not induce a viremia that could infect a fetus. In addition, a canarypox-vectored influenza vaccine available in Europe is licensed for use in horses during pregnancy; therefore the vectored WNV vaccine is unlikely to be associated with an increased risk of adverse effects in pregnant mares. Similarly, data currently

under review by the USDA from studies involving a large number of pregnant mares suggest that PreveNile will likely also be shown to be safe for use in pregnant mares (Vaala W, personal communication, 2007). As with other vaccines, it is sound practice to avoid administering West Nile vaccines to mares during the first 60 days of gestation unless conditions of imminent risk prevail.

Booster vaccination of previously primed pregnant mares 4 to 8 weeks before foaling appears to induce a strong anamnestic serologic response that provides their foals with passive colostral protection lasting at least 3 to 4 months.[37] In contrast, a significant proportion of naive pregnant mares failed to seroconvert when the primary series of WNV—Innovator vaccine was administered during the second half of gestation, perhaps reflecting pregnancy-associated downregulation of Th2 responses.[37] This observation adds further justification to the recommendation that when inactivated West Nile—Innovator vaccine is used, the primary series is best completed before breeding. In a similar study, pregnancy did not appear to suppress the response of mares to primary immunization with Recombitek (Wilson WD and colleagues, unpublished observations, 2007).

In contrast to findings with many other vaccines in the foals of immune mares, MDAs do not block the response of foals as young as 3 months of age to vaccination with either the inactivated or the recombinant vaccine.[37] Although this finding is somewhat surprising for the inactivated vaccine, it might reasonably have been expected for the recombinant vaccine because the canarypox vector system accomplishes transfection of cells and expression of the major E-peptide and M-peptide antigens of WNV on the surface of antigen presenting cells (APCs) in association with major histocompatibility complex (MHC) class I and class II antigens. These peptide antigens are therefore not free in the tissues and circulation to be neutralized by MDAs.

Primary vaccination of foals from properly vaccinated mares can be started by administration of the first dose of either West Nile—Innovator or Recombitek as early as 3 to 4 months of age, followed by a second dose approximately 1 month later, then a third dose 8 to 16 weeks after the second dose. This third dose increases the likelihood that foals with high MDA levels, which may have attenuated the response to the first dose of vaccine, will become primed and protected. Even in foals that have no maternally derived WNV antibodies after nursing, the third dose of inactivated vaccine in the primary series induces significantly higher and more persistent levels of antibody than do two doses. A booster should be administered during the spring of the yearling year, after which the recommendations for vaccination of adult horses should be followed. Primary vaccination of foals from unvaccinated, unexposed mares should commence at 3 months of age or younger (as early as 1 month of age), depending on month of birth and seasonal level of activity of mosquito vectors in the area. The three-dose primary vaccination protocol previously outlined should be followed. Revaccination should be performed before the onset of the next mosquito season.

The influence of MDAs on the response of foals to PreveNile has not been established, but the product is labeled for administration of a single priming dose to foals 5 months of age or older. A second dose of vaccine should be administered before the onset of the next mosquito season. Considering the rapid onset of immunity induced by this vaccine, protection can likely be accomplished at a similar age to that induced when the primary series with the inactivated or canarypox-vectored vaccines is started at 3 to 4 months of age. Preliminary data suggest that the plasmid DNA WNV vaccine may also circumvent the potentially interfering effects of MDAs.[13]

Horses that have recovered from clinical WNV infection will likely be protected for the remainder of their lives and should not need to be revaccinated unless changes in their immune status, as might occur with prolonged corticosteroid administration, alter their susceptibility to infection.[64]

It is remarkable that in little more than 6 years after WNV disease was first encountered in the Americas, four vaccines with documented efficacy based on challenge studies have been licensed for the benefit of horses, including three that apply the most modern technologies available for either animals or humans at this point in time.

48.4.4 Rabies

Rabies is an infrequently encountered neurologic disease of equids resulting from inoculation of the rabies virus through the bite of infected (rabid) wildlife. Wildlife species that serve as the natural reservoirs for infection with this rhabdovirus differ among regions of North America but include raccoons, foxes, skunks, and bats. Horses most often sustain bites on the muzzle, face, or lower limbs. The rabies virus then migrates via nerves to the brain, where it initiates rapidly progressive encephalitis. Even though the incidence of rabies in horses is low, the disease is invariably fatal and has considerable public health significance. All horses kept in areas where rabies is endemic in the wildlife population are at risk and should be vaccinated as part of the core vaccination program. Therefore it is recommended that horses be vaccinated against rabies by, or under the direct supervision of, a veterinarian using one of the three inactivated, tissue culture—derived products currently licensed for use in horses (Rabvac 3, Fort Dodge; RM Imrab 3, Merial; and Rabguard TC, Pfizer). These vaccines are potent immunogens that induce strong serologic responses that peak within 28 days after intramuscular administration of a single dose.

1575

1576

Although correlates for protection against infection with rabies virus in horses are not well defined, it is logical to assume that protection correlates with titers of circulating antibody. In humans, postvaccination antibody titers are used to predict protection. In dogs, however, postvaccination serologic test results were not found to be completely predictive of resistance to challenge exposure during tests performed with certain inactivated vaccines.[65] Challenge studies demonstrating efficacy are required for licensing of all rabies vaccines, including those labeled for use in equids in the United States; however, published results are not available. The challenge studies are conducted by the vaccine manufacturers as outlined in the Code of Federal Regulations (CFR) from the USDA. These studies indicate a DOI of 12 months, and a minimum of 80% of vaccinated animals must be resistant to severe challenge with rabies virus.

For primary immunization, label directions on inactivated rabies vaccines licensed for use in horses suggest administration of one dose to horses age 3 months or older followed by a second dose 1 year later. Thereafter, annual revaccination is recommended. Although none of the licensed vaccines carries a specific label approval for use in pregnant mares, it is important to acknowledge that only a limited number of equine vaccines are specifically licensed for use in pregnant mares, and veterinarians do administer inactivated rabies vaccines to pregnant mares. Alternatively, veterinarians may recommend that mares be vaccinated against rabies before breeding in order to reduce the number and type of vaccines given in the period before foaling. Because rabies antibodies persist in serum for a prolonged period, foals born to mares that are revaccinated while open acquire substantial titers of rabies antibody after ingesting colostrum.

Documentation of rabies in reportedly vaccinated horses, most of which were less than 2 years of age, has brought into question the efficacy of label recommendations for primary vaccination of foals against rabies.[66] Recent studies in our laboratory have shown that the serologic response of most 3-month-old foals from antibody-positive mares is completely blocked, even when a two-dose primary vaccination series is used. Although the response to the first dose of vaccine is typically blocked in 6-month-old foals from antibody-positive mares, these foals appear to seroconvert after administration of a second dose 4 weeks later. Primary vaccination of foals from vaccinated mares should therefore be delayed until they are 6 months of age or older

and should include 2 doses of inactivated vaccine administered approximately 4 weeks apart, followed by a third dose at 1 year of age. For foals from unvaccinated mares the primary vaccination series can be started according to manufacturers' recommendations as early as 3 months of age and may consist of only one dose, although a two-dose series will likely induce more durable immunity.

48.4.5 Equine Influenza

Infection of the respiratory tract of horses with the orthomyxovirus influenza A/equine/2 (H3N8), remains one of the most common causes of rapidly spreading outbreaks of respiratory disease, despite the widespread practice of frequently revaccinating horses with inactivated vaccines by intramuscular injection. The influenza A/equine/1 subtype (H7N7) has not been recognized as a cause of clinical disease for many years and is likely extinct in nature. Influenza is endemic in the equine populations of the United States and much of the world, with the notable exceptions of New Zealand and Iceland. Rapid national and international transportation of horses facilitates spread of the virus. Concentrating young horses at racetracks, training facilities, boarding stables, breeding farms, shows, or similar athletic events increases the risk of infection, as does a low serum concentration of specific antibody.[67] Older horses are generally less susceptible to infection but may become ill when partial protection is overwhelmed by exposure to horses excreting large amounts of virus. Explosive outbreaks occur at intervals of several years when the immunity of the equine population wanes and sufficient antigenic drift has occurred to generate a new viral strain. In contrast to herpesviruses, equine influenza virus is not maintained in asymptomatic carrier horses and does not circulate constantly, even within large groups of horses. Rather, the disease is introduced sporadically by a symptomatic or asymptomatic infected horse. This epidemiologic finding and the rapid elimination of the virus by the equine immune response suggest that infection can be avoided by preventing entry of the virus into an equine population (e.g., by quarantine of newly arriving horses for at least 14 days) and by appropriate vaccination.[68]

Equine influenza virus is highly contagious and spreads rapidly through groups of horses in aerosolized droplets dispersed by coughing. Contaminated buckets, grooming or feeding equipment, tack, and transport vehicles may serve as fomites because the virus can survive for hours on such objects. Severity of clinical signs of influenza, which include nasal discharge, fever, lethargy, anorexia, cough, and myalgia, depends on the degree of existing immunity and other factors. Infected horses shed virus for up to 10 days in their nasal secretions. Inactivated vaccines do not induce sterile immunity; therefore recently vaccinated horses can become infected, shed virus, and contribute to interepidemic persistence of infection within the equine population and propagation of infection during outbreaks.[19]

Immunity to the same (homologous) strain of H3N8 virus after natural infection persists for more than a year and involves both local and systemic humoral and cellular mechanisms These include induction of large amounts of virus-specific neutralizing IgG and secretory IgA antibody in nasal secretions, high levels of circulating IgG antibodies, and genetically restricted antigen-specific cytotoxic T lymphocytes (CTLs) that kill infected cells.[69–73] Memory CTLs can be detected in peripheral blood for at least 6 months after infection, and solid immunity persists even when circulating antibody titers have declined to low or undetectable levels.[70,71,74,75] Similarly, protection induced by the licensed modified live intranasal influenza vaccine (Flu-Avert IN, Intervet) is presumably mediated through induction of local immune responses in the respiratory tract, because this vaccine does not typically induce high levels of circulating antibody.[6,8] With the possible exception of ISCOM vaccines, inactivated vaccines administered by intramuscular injection have limited potential to induce CTL or nasal secretory IgA responses and induce only low levels of neutralizing antibody in nasal secretions.[69,75,76] The degree of protection induced by inactivated influenza vaccines is highly correlated

with postvaccination titers of circulating antibody, predominantly of the IgGa and IgGb subisotypes, as measured by HI or single radial hemolysis (SRH) tests.[67,77–80] SRH levels ≥100 mm^2 are considered to be at least partially protective; however, levels >140 mm^2 are required for successful prevention of disease.[79] The partial protection induced by inactivated vaccines is of limited duration (up to approximately 7 months, depending on the vaccine) and is manifested as a reduction in clinical signs and attenuation of viral shedding in horses exposed to infection.[68,69]

1576

1577

The magnitude of the serologic response to inactivated influenza vaccines depends on many factors, the most important of which are the quality and quantity (mass) of the viral antigen and the choice of the adjuvant.[79,81,82] Carboxypolymer-based compounds (carbomer, Carbopol) and ISCOMs are contained in some of the most efficacious inactivated influenza vaccines, whereas some commonly used adjuvants such as alum have been associated with induction of unproductive immune responses.[69,81] History of previous vaccination or infection, interval since the last dose of vaccine, antibody titer at the time of vaccination, age, maternal antibody status, and relatedness of the vaccine strain to circulating field strains of influenza virus are other important determinants of efficacy, at least for inactivated influenza vaccines.[77,83,84] Antigenic drift of the A/equine/2 subtype has resulted from point mutations in the genes encoding the amino acid sequences of the hemagglutinin (H) and neuraminidase (N) glycoprotein antigens on the surface of the virus. The result is emergence of viral strains representing two antigenic lineages, American and Eurasian, of the H3N8 virus. Further antigenic drift within each lineage has generated variants that, as with the prototypic strain A/equine/2/Miami 63, are named according to the location and year in which they were first isolated. Antigenic drift, by generating antigenically heterologous viruses, reduces the degree and duration of protection conferred by previous infection or vaccination because of the specificity of immunoglobulins, and it allows horses with high titers to become infected and develop clinical signs of disease if the vaccine strain is not closely related to the drifted infectious field strain.[85] Although antigenic drift of equine influenza viruses is slower than that of human influenza viruses, it is recommended that inactivated equine influenza vaccines include viral antigens from isolates obtained within the most recent 5 years and, ideally, representatives of both the American and Eurasian lineages. An expert surveillance panel meets annually to recommend strains that should be included in influenza vaccines in subsequent years (www.equiflunet.org.uk). In order to comply with federal regulations for licensing and marketing of vaccines, any change of a vaccine, such as including the most recently isolated influenza virus, usually leads to costly and time-consuming evaluation of the revised product. Consequently, viral antigens contained in inactivated vaccines typically lag more than the recommended 5 years behind the antigenic drift of field viruses, resulting in suboptimal protection. Even though Flu-Avert IN contains only a 1991 H3N8 strain of North American lineage, it has been shown to be protective against challenge with Eurasian strains and recently isolated North American strains.

The short-lived immunity after vaccination with inactivated equine influenza vaccines was the impetus for past recommendations for frequent revaccination, at intervals as short as 2 months. However, too short an interval between revaccination may compromise efficacy because influenza vaccination in a horse with a high antibody titer inhibits development of an optimal anamnestic response.[86] An additional consideration that potentially limits the efficacy of influenza vaccines is the phenomenon termed “original antigenic sin,” whereby horses exposed to a drifted field A/equine/2 virus will mount an anamnestic immune response directed more strongly against the strain with which they were vaccinated initially than against the drifted field virus.[82]

A considerable amount of published efficacy data, based both on challenge studies and on field epidemiology studies, has been available for many years in Europe to support the use of influenza vaccines. In contrast, information regarding the efficacy of influenza vaccines marketed in North America has remained sparse until

recently. Furthermore, studies conducted in North America during the late 1990s showed that the inactivated influenza vaccines in use at the time failed to provide much benefit in terms of reducing the risk of infection and clinical disease during field outbreaks.[19,67] Serologic testing performed during these and other studies indicated that vaccine failure was caused by failure of the influenza vaccines in use at the time to induce protective antibody titers.[19,67,87]

Fortunately, vaccine manufacturers in North America have responded to the challenge of producing more efficacious equine influenza vaccines during the last few years by incorporating more relevant recent viral strains, by increasing antigenic mass of relevant strains, by eliminating the seemingly irrelevant H7N7 strain, by modifying adjuvant systems, and by introducing novel technologies. An important advance occurred in 1999 when Heska Corporation marketed an attenuated live, cold-adapted influenza vaccine (Flu-Avert IN, Intervet, Millsboro, Del.) for intranasal administration. This vaccine, which contains a Kentucky/1991 strain of North American lineage, was found to be highly efficacious in blinded, controlled challenge studies conducted 5 weeks, 6 months, and 1 year after administration of a single dose to naive horses.[8] Subsequently Flu-Avert IN was shown to cross-protect against European H3N8 strains, as well as against North American strains isolated during the late 1990s and early 2000s, and to induce a rapid onset of protection within 7 days of administration of a single dose to naive horses.[6,88] Although horses challenged 1 year after administration of a single dose showed a significant, but only partial, reduction in severity of clinical signs and virus shedding, a more marked reduction in clinical signs and viral shedding was found when the challenge was performed 6 months after vaccination.[8] Based on these results, revaccination at 6-month intervals is recommended. Field experience indicates that this regimen induces solid clinical protection after natural challenge. Currently Flu-Avert IN is licensed for use in nonpregnant horses 11 months of age or older, primarily because this was the youngest age of the horses used in the challenge studies for licensing. Horses may shed small amounts of vaccinal virus for several days after vaccination with Flu-Avert IN, but the amount of virus shed is so low that in-contact horses will not generally become infected or immunized with vaccinal virus shed by recently vaccinated horses, and the likelihood of reversion to virulence is extremely low.[7]

Recently updated inactivated influenza vaccines have demonstrated good efficacy in challenge studies. Inactivated influenza vaccines containing one or more relevant H3N8 strains are currently marketed by Boehringer Ingelheim (Calvenza EIV) and Fort Dodge Animal Health (Fluvac Innovator). These and other companies also market a large number of multicomponent combination vaccines that contain the same inactivated influenza antigens as are in their single-component products but also contain tetanus, WEE and EEE virus, EHV, or WNV antigens. Calvenza EIV is adjuvanted with Carbopol and is the only inactivated vaccine currently licensed in North America that contains antigens from H3N8 viruses of both the American and European lineages (Kentucky/95 and Newmarket/2/93).

The initial two doses of this vaccine are administered IM; subsequent doses may be administered IM or intranasally. It is proposed, but not proved, that administration of booster doses by the intranasal route may provide a stronger local mucosal immune response. This vaccine is licensed for use in horses older than 6 months of age, including pregnant mares. Fluvac Innovator contains a KY/97 H3N8 strain in a metabolizable oil (MetaStim) adjuvant.

In late 2006, Merial was granted a North American license to market an injectable canarypox-vectored recombinant equine influenza vaccine that has been used with success in Europe for several years. This vaccine, named Recombitek Equine Influenza Virus vaccine, has been shown to induce strong protection in challenge studies and shows great potential to have a positive impact on influenza prevention in North America.[14] The vaccine incorporates the HA gene from the Kentucky/94 and Newmarket/2/93 H3N8 strains into the same

vector delivery platform as the efficacious WNV virus vaccine (Recombitek) and contains a carbomer polymer adjuvant in the diluent.[14] Consequently, this vaccine invokes a broad array of humoral and cellular immune responses. Challenge studies document onset of protection as soon as 2 weeks after completion of a two-dose primary series and persistence of solid protection for at least 5 months. Administration of a booster dose at 5 months induced a strong anamnestic response that provided solid protection persisting for at least 12 months.[18] Preliminary evidence suggests that this canarypox-vectored influenza vaccine will be able to circumvent the inhibitory effect of maternal antibodies, an issue that significantly affects primary immunization of foals using inactivated influenza vaccines.[89] Recombitek Equine Influenza Virus vaccine is licensed for vaccination of healthy horses as young as 5 months of age.

48.5 VACCINATION PROTOCOLS FOR INFLUENZA

The following are options for primary vaccination of adult horses that have not previously been vaccinated:

- Flu-Avert—Administer a single dose intranasally. A second dose administered 3 months later may be beneficial, particularly for horses vaccinated at less than 11 months of age.
- Recombitek Equine Influenza Virus vaccine—Administer two doses, 5 weeks apart.
- Inactivated IM administered vaccines—Administer two doses, 3 to 6 weeks apart, according to label directions. Although not specifically recommended by some manufacturers, administration of a third dose of vaccine, 2 to 6 months after the second dose, is indicated because it significantly enhances the magnitude of the primary response and duration of persistence of antibodies at protective levels.

Routine revaccination at an interval of 6 months appears to be appropriate for the intramuscularly administered inactivated and intranasally administered modified live virus influenza vaccines currently marketed in North America. A revaccination interval of 12 months is recommended for the recombinant vaccine, although this recommendation has not yet been tested in the field setting in North America. These “routine” revaccination protocols should be customized, by adjusting timing of boosters or inclusion of an additional booster, to achieve maximum protection during periods when the risk of exposure is high. For example, strategic revaccination 1 month before being placed at high risk of exposure, such as at a show or sale, or being transferred to a training or boarding facility is justified to maximize protection.

Revaccination of pregnant mares 4 to 8 weeks before foaling with a vaccine that stimulates a robust serologic response is recommended. Although the intranasally administered Flu Avert IN vaccine induces good protection, it does not routinely stimulate high levels of circulating antibody, at least when used for primary immunization. An inactivated or canarypox-vectored recombinant injectable vaccine is therefore recommended at this time for prefoaling booster vaccination of pregnant mares.[37]

48.5.1 Vaccination of Foals

The antibody status of a mare at the time of foaling is the main determinant of the postnursing circulating antibody titer in her foal and therefore has a profound impact on the ability of the foal or weanling to respond to influenza vaccines administered during the first year of life. Foals born to seronegative, unvaccinated mares respond appropriately to influenza vaccines; therefore primary vaccination can commence at 3 months of age or younger if significant risk of exposure to influenza exists. In contrast, maternal antibodies have been shown to completely block the serologic response of foals to a primary immunization series composed of two or more

doses of inactivated influenza vaccines when the first dose is administered when the foal is younger than 6 months of age.[23–29,35] Interference from MDAs may persist until 9 months of age or beyond for foals with high antibody titers postnursing; therefore primary vaccination of foals from immune mares should be delayed as long as possible, and preventive measures should focus on preventing introduction of infected horses.* Studies in Newmarket, United Kingdom, have shown that influenza virus infection is rare in thoroughbred yearlings before they enter training, suggesting that the risk of influenza is low in horses younger than 1 year of age born to mares in herds that are well vaccinated.[84,91,92] Therefore there appears to be little justification to vaccinate young foals from vaccinated mares against influenza, as was recommended in the past.[54,93,94]

The intranasal modified live vaccine (Flu-Avert IN) is licensed for vaccination of horses 11 months of age or older. Whereas this vaccine has been shown to be safe in foals as young as 2 months of age,[95] published data regarding the potential for MDAs to interfere with the response are lacking. Unpublished observations suggest that MDA interferes with the response of foals aged 3 to 6 months, whereas foals with maternal antibody vaccinated at 7 months of age were protected against virulent challenge (Holland and Chambers, personal communication, 2000). Pending publication of well-controlled studies, it is recommended that if the first dose of Flu-Avert IN vaccine is administered before 11 months of age, a second dose should be administered at 11 months of age or older.[96] The European-licensed live canarypox-vectored recombinant influenza is labeled for use in pregnant mares and foals as young as 4 months of age.[75] The North American—licensed Recombitek Equine Influenza Virus vaccine has been shown to be safe in foals as young as 4 months, but the minimum age recommended for vaccination of foals from immunized dams is 5 months. Effective priming has been documented after administration of the first dose of the vectored vaccine to foals aged 10 to 20 weeks that had detectable MDAs at the time of vaccination.[89] If the foal experiences failure of passive transfer of maternal antibodies or if the mare is seronegative for influenza, vaccination can commence at 4 months of age but should include an additional dose in the primary series.

The decision whether to vaccinate in an outbreak is dependent on many factors, the most important of which are the age, vaccination status, and size of the population of horses at risk; the elapsed time since onset of the outbreak; the rapidity with which a diagnosis can be confirmed; the layout of the physical facilities; and availability of personnel. Rapid (same-day) diagnosis of influenza should be pursued during outbreaks of contagious respiratory disease and can be accomplished using the highly sensitive and specific polymerase chain reaction (PCR) test or antigen-capture ELISA. Outbreaks of influenza at racetracks and similar large facilities typically take 1 month or more to spread through the entire population; therefore sufficient time exists to enhance immune protection of many at-risk horses while implementing other management strategies to minimize disease spread.[88] It is prudent to booster vaccinate those horses that have been on a regular influenza vaccination program but have not been revaccinated within the previous 3 months. It is also important to induce protection as quickly as possible in horses that have not previously been vaccinated. Of the vaccines currently available, Flu-Avert IN induces protection most rapidly, within 7 days of administration of a single intranasal dose; therefore this is currently the product of choice for vaccination of naive horses and those of unknown vaccination status in the face of an outbreak.[88] There is no evidence to suggest that any adverse effects occur when Flu-Avert IN is administered to horses that are incubating infection, although vaccination of horses that are already clinically ill is not recommended. Preliminary evidence suggests onset of immunity within 14 days of administration of one dose of the canarypox-vectored vaccine; therefore use of this vaccine would likely also prove useful in controlling outbreaks.

48.6 FUTURE INFLUENZA VACCINES

In addition to the modified canarypox-virus vector described earlier,[14] a recombinant modified vaccinia Ankara (rMVA) vector that delivers genetic material encoding for relevant HA antigens of an H3N8 influenza virus has been developed.[97,98] The rMVA system is designed to focus the CTL response on the recombinant antigen and was initially tested in a prime-boost strategy in which the priming dose consisted of a DNA plasmid encoding for expression of the HA antigen. The intent of this DNA prime-rMVA boost regimen was to invoke both cellular and humoral immune responses involved in protection.[97] A subsequent study showed that the rMVA system was capable of inducing virus-specific lymphoproliferative and interferon gamma (IFN-γ) mRNA responses; antigen-specific IgGa, IgGb, and IgA antibodies; and protection from challenge, both with and without a priming dose of the DNA vaccine.[98] These data indicate that vaccination of horses with rMVA alone, or as part of a prime-boost regimen, is an effective means of inducing protective immunity to influenza virus infection.[98] Considerable research has been performed to document the efficacy of the DNA vaccine used in the previously mentioned studies against equine influenza. However, the delivery system used (multiple sublingual, conjunctival, and subcutaneous injections delivered with a gene gun with the patient under general anesthesia) is impractical for use in the field.[98,99] Recent licensing of a naked plasmid DNA vaccine that can be conveniently administered to horses by intramuscular injection to prevent WNV infection clearly documents the potential for development of a DNA vaccine to prevent influenza in horses in the future.

48.6.1 Equine Herpesvirus (Rhinopneumonitis)

The respiratory tract is the primary route of infection for both EHV-1 and EHV-4, both of which cause respiratory tract disease that varies in severity from subclinical to severe and is characterized by fever, lethargy, anorexia, nasal discharge, and cough.[100] Seroepidemiologic studies indicate that the vast majority of foals become infected with EHV-1 and EHV-4 during the first few months of life, but the clinical disease syndromes resulting from these infections are not always well defined, perhaps reflecting the modulating effect of MDAs.[101–103] Recurrent or recrudescent clinically apparent infections are seen in weanlings, yearlings, and young horses entering training, especially when horses from different sources are comingled.[100,104] In contrast, surveillance studies involving racehorses document that seroconversion to both EHV-1 and EHV-4 occurs sporadically during the course of a racing season, but these seroconversions are often not clearly associated with outbreaks of respiratory disease that follow an epidemiologic pattern consistent with an infectious agent.[105,106] EHV-1 and EHV-4 are spread by direct and indirect (fomite) contact with nasal secretions, by aerosolized secretions from infected horses, and, in the case of EHV-1, by aborted fetuses, fetal fluids, and placentas associated with abortions. Management practices are therefore of primary importance for control of clinical disease caused by EHVs.

Viremia occurs frequently after infection with EHV-1, potentially leading to paralytic neurologic disease (myeloencephalopathy) secondary to vasculitis of the spinal cord and brain, abortion of virus-infected fetuses, or birth of infected nonviable foals. In contrast, manifestations of infection with EHV-4 (rhinopneumonitis) are generally confined to the respiratory tract because EHV-4 does not typically infect endothelial cells or produce a cell-associated viremia.[107] As with herpesvirus infections in other species, horses typically fail to clear primary infections with either EHV-1 or EHV-4, the result being that most horses in the population remain latently infected with both viruses.[100,103,108] Latently infected horses do not show clinical signs but may experience recrudescence of infection, with or without clinical signs, an increase in antibody titer, and shedding

of the virus when stressed. Consequently, many horses have detectable levels of virus-neutralizing (VN) antibody to both EHV-1 and EHV-4 in their serum.[101,108] These features of the epidemiology of herpesvirus infections seriously compromise efforts to control these diseases and explain why outbreaks of EHV-1 or EHV-4 can occur in closed populations of horses. Whereas most mature horses have developed some immunity to EHV-1 and EHV-4 through repeated natural exposure and do not typically show respiratory signs when they become reinfected, horses do not appear to become resistant to the abortigenic or neurologic forms of infection with EHV-1, even after repeated exposure.[109] In fact, mature horses previously exposed are more likely to develop the neurologic form of the disease than are juvenile horses.[110,111]

Correlates for protection against EHV-1 and EHV-4 infection have been investigated extensively but are not yet clearly defined. Infection with EHV-1 induces a strong humoral response, but protection from reinfection is short-lived and is not achieved until the horse has experienced multiple infections with homotypic virus.[100,107] No clear relationship exists between protection from EHV-1 infection and concentrations of circulating antibody induced by vaccination or infection, but the duration and amount of virus shedding from the nasopharynx is reduced in animals with high levels of circulating neutralizing antibody.[107] Mucosal immunity and cell-mediated responses likely play a role at least as important as circulating neutralizing antibodies in protection against EHV-1 infection,[112] because the presence of MHC class 1—restricted CTL precursors in peripheral blood is correlated with protection.[107] Because EHV-4 replication is largely confined to epithelial cells of the upper respiratory tract, it is likely that mucosal immunity is important in protection.[107] Whereas circulating antibodies alone do not prevent EHV-4 infection, high levels of vaccine-induced circulating VN antibody markedly reduce virus shedding and clinical signs after challenge infection.[107,113–115]

Various killed vaccines are available, including those licensed only for protection against respiratory disease; currently all contain a low antigen load, and two (Pneumabort-K+1b, Fort Dodge Animal Health, and Prodigy, Intervet) that are licensed for protection against both abortion and respiratory disease contain a high antigen load. Performance of the killed low—antigen-load respiratory vaccines is variable, with some vaccines outperforming others. Performance of the killed high—antigen-load abortion and respiratory vaccines is superior, resulting in higher antibody responses and some evidence of cellular responses to vaccination. This factor may provide good reason to choose the high—antigen-load abortion and respiratory vaccines when the slightly higher cost is not a decision factor. A single manufacturer provides a licensed modified live EHV-1 vaccine, which to date has not been compared directly with high—antigen-load respiratory and abortion vaccines. This modified live vaccine has been shown to offer superior clinical protection and reduce viral shedding in a comparison with a single killed low—antigen-load respiratory vaccine.[116] Vaccination with either EHV-1 or EHV-4 can provide partial protection against the heterologous virus, and vaccines containing EHV-1 may be superior in this regard.

1579

1580

The principal indication for use of EHV vaccines is prevention of EHV-1—induced abortion in pregnant mares and reduction of signs and spread of respiratory tract disease (rhinopneumonitis) in foals, weanlings, yearlings, and young performance and show horses that are at high risk of exposure. Many horses do produce postvaccinal antibodies against EHV, but the presence of those antibodies does not ensure complete protection. Consistent vaccination appears to reduce the frequency and severity of herpesvirus-induced disease. Although convincing evidence is lacking, field experience suggests that, whereas the incidence of sporadic EHV-1—induced abortion in individual mares has not changed, the incidence of abortion storms caused by EHV-1 has declined significantly since the introduction and widespread use of EHV-1 vaccines in the United States.[108,109] Outbreaks of abortion and associated perinatal foal death, however, do continue to occur on occasion in herds of vaccinated mares.

Of the vaccines currently licensed for use in pregnant mares in North America, only inactivated monovalent EHV-1 vaccines (Pneumabort-K+1b, Fort Dodge Animal Health, and Prodigy, Intervet) containing abortigenic strains of EHV-1 carry a label claim for preventing abortion, whereas at least one bivalent EHV-1/4 vaccine is licensed for prevention of abortion in Europe (Duvaxyn EHV-1/4, Intervet). One of the vaccines available in North America, Pneumabort-K+1b, incorporates both the 1p and 1b subtypes of EHV-1 to reflect the documented increase in the proportion of EHV-1 abortions caused by the 1b subtype that occurred during the 1980s as compared with earlier years.[117] Pregnant mares should be vaccinated during the fifth, seventh, and ninth months of gestation. Many veterinarians also recommend a dose during the third month of gestation. Similarly, vaccination of mares with an inactivated EHV-1/EHV-4 vaccine at the time of breeding and again 4 to 6 weeks before foaling is commonly practiced to enhance concentrations of colostral immunoglobulin for transfer to the foal. However, no published reports document the effectiveness of this approach in raising titers of specific antibody in mares that have already been vaccinated against EHV-1 three times during the previous 5 months. Vaccination of barren mares and stallions with either a bivalent EHV-1/4 vaccine or a monovalent EHV-1 vaccine before the start of the breeding season, and thereafter at 6-month intervals, is recommended, with the goal of increasing herd immunity in an attempt to reduce viral shedding and challenge to pregnant mares on breeding farms.[108]

The modified live virus EHV-1 vaccine (Rhinomune, Pfizer) has been used as an aid to prevention of EHV-1 abortion by some practitioners for many years,[118] even though this vaccine is not currently labeled for this use. However, several recent developments have created a renewed interest in the potential for use of modified live virus vaccines for protecting horses against manifestations of EHV-1 and EHV-4 infection. Sequencing of the EHV-1 genome has made it possible to document the nature of the mutation encoding for attenuation, mediated through truncation of the gp2 glycoprotein, of the KyA strain.[119] Similar studies may soon yield information regarding the mutation underlying attenuation of the RAC-H strain from which Rhinomune was derived.

Because currently available inactivated vaccines do not block infection with EHV, the most we can hope for when using inactivated vaccines is reduction of severity of clinical signs and attenuation of virus shedding to help protect herdmates. Challenge studies in weanlings aged 5 to 8 months have clearly demonstrated the efficacy of an inactivated whole virus EHV-1/4 vaccine in reducing clinical manifestations and virus shedding induced by virulent EHV-1 challenge administered 2 weeks after completion of the two-dose primary series.[114] Efficacy was clearly correlated with vaccine-induced antibody levels at the time of challenge in this study.[114]

Specific antibodies against both EHV-1 and EHV-4 are passed in colostrum.[32,33,36,120,121] Field studies with EHV-1 modified live vaccines indicate that colostral antibodies exert a profound inhibitory effect on serologic responses to vaccination up to at least 5 months of age.[32,122,123] However, a cytotoxic cellular immune response to both EHV-1 and EHV-4 was induced in a substantial percentage of foals vaccinated with an EHV-1 modified live vaccine in the presence of maternal antibody, even though humoral responses were often absent.[124] It is uncertain whether these responses would provide protection against natural challenge. Recent studies with two different commercially available inactivated bivalent EHV-1/4 vaccines and one inactivated EHV-4/influenza vaccine showed that the majority of foals from EHV-vaccinated mares do not mount a detectable neutralizing antibody response to vaccines administered at 3 and 4 months of age, even when three doses are administered in the primary series.[33,35,36] An increased proportion of foals responded when vaccinated with a three-dose series starting at 5 or 6 months of age, but a substantial number still failed to seroconvert.[35,36] Some foals with low or undetectable levels of SN antibody at the time of vaccination failed to mount a serologic response, suggesting that low levels of antibody, below the lower limit of detection of the SN test based on

EHV-1 antigen, are capable of inhibiting the serologic response to inactivated EHV-1/4 vaccines.[36] The failure of a large proportion of foals less than 6 months of age to mount serologic responses to inactivated EHV-1/4 vaccines and the influence of antibody titer at the time of vaccination on failure to respond has been confirmed using sensitive gD and gG ELISAs in studies on commercial stud farms in Australia.[125] In parallel studies, these researchers concluded that mares were the source of infection for foals and that intensive use of inactivated EHV-1/4 vaccines on breeding farms in Australia had minimally affected the infection rate of young foals and weanlings with EHV-1 and EHV-4.[101,103,126]

Considering the uncertainty regarding the role of EHV-1 and EHV-4 as causes of clinically important respiratory disease, the lack of published data regarding the efficacy of available vaccines in preventing infection and establishment of latency, and results of a recent study documenting the poor serologic responses of naive horses to a number of killed low—antigen-load EHV respiratory vaccines currently marketed in North America,[20] there appears to be little rationale to support the common practice of frequent revaccination of foals, weanlings, yearlings, and young performance horses against EHV-1 and EHV-4.[5] Furthermore, an obvious dilemma in designing a vaccination strategy to prevent EHV-1 and EHV-4 infection in foals and weanlings is that if primary immunization is delayed until 6 months of age or older to reduce the likelihood of MDA interference, foals are likely to encounter field infection before the three-dose primary series can be completed. 1580
Thus it is unreasonable to expect a high degree of efficacy for vaccination programs designed to protect foals 1581
and weanlings against EHV infection using available vaccines. Despite these uncertainties, many practitioners elect to vaccinate against both EHV-1 and EHV-4. Under these circumstances, a reasonable compromise would be to start foal vaccination at 4 to 6 months of age using two doses of an inactivated bivalent vaccine or an EHV-1 modified live vaccine administered 3 to 4 weeks apart, followed by administration of a third dose 8 to 12 weeks later. Revaccination at 4- to 6-month intervals thereafter using either an inactivated bivalent vaccine or a modified live EHV-1 vaccine appears appropriate for yearlings and young performance or show horses that experience contact with other horses. Frequent vaccination of nonpregnant mature horses, except those on breeding farms, with EHV vaccines is generally not indicated.

Available vaccines make no labeled claim to prevent the myeloencephalopathic form of EHV-1 infection (EHM). However, recent outbreaks of EHM in populations of horses in several regions of North America have prompted many racing jurisdictions and managers of equine facilities and events to impose EHV-1 vaccination requirements for incoming and resident horses in the hope that EHV-1 infection and development of EHM can be prevented. The efficacy of this approach remains to be proven. In fact, frequent revaccination of mature horses to prevent the neurologic form of EHV-1 is not clearly justified in most circumstances because EHM is a relatively rare disease from a population standpoint and most mature horses have previously been infected with EHV-1 and are latent carriers. Currently available vaccines do not reliably block infection, development of viremia, or establishment of latency, and EHM has been observed in horses vaccinated against EHV-1 regularly at 3- to 5-month intervals with inactivated or modified live vaccines.[110,111,127,128] Furthermore, vaccination has been cited by some as a potential risk factor for development of neurologic EHV-1, although evidence to support this opinion is far from conclusive.[129]

The genetic basis underlying the apparent increased likelihood that some EHV-1 isolates will cause EHM has only recently been described and involves a single point mutation in the DNA polymerase *(DNApol)* gene.[130] This mutation results in the presence of either aspartic acid (D) or an asparagine (N) residue at position 752. More than 80% of EHV-1 isolates associated with EHM are of the D_{752} form, whereas less than 20% are of the N_{752} form.[130] Isolates of the D_{752} form have been designated “neuropathogenic strains” in recent publications, lay articles, and laboratory PCR result reports, whereas N_{752} isolates have been designated as “wild-type,”

"abortigenic," or "nonneuropathogenic." The latter terminology is unfortunate because both the D_{752} and the N_{752} isolates are capable of inducing all syndromes (i.e., respiratory disease, abortion, neonatal death, and EHM).

A challenge study performed almost 30 years ago to test the efficacy of Pneumabort K in preventing abortion and a recent study to test the efficacy of Rhinomune against challenge with a "neuropathogenic" strain of EHV-1 provided some evidence that these vaccines may have a place in control of outbreaks of EHM.[113,116] Of interest, the Army 183 EHV-1 strain used as the challenge virus in the Pneumabort K efficacy study has now been shown to carry the D_{752} mutation, as has the Findlay '03 strain used in the Rhinomune study. However, the low numbers of horses used in these studies, the failure of either vaccine to prevent infection or significantly reduce the level of viremia, the lack of statistical significance of results pertaining to prevention of neurologic signs, and the well-known difficulties encountered in accomplishing a consistent and reproducible challenge model for neurologic EHV-1 infection justify caution in interpretation. However, the significant reduction in viral shedding observed in vaccinated horses provides reasonable justification for booster vaccination of unexposed horses that are at risk for infection in order to reduce viral shedding in the event that they do become exposed to EHV-1. Through enhancement of herd immunity, it is hoped that the level of infectious virus circulating in the at-risk population will be reduced and that, in turn, the risk that individual horses in the population will develop disease will be reduced.[128] This approach also relies on the assumption that the immune system of most mature horses has already been "primed" by prior exposure to EHV-1 antigens through field infection or vaccination and can therefore be "boosted" within 7 to 10 days of administration of a single dose of vaccine. Although the validity of this approach has not been critically evaluated for the prevention of EHV-1 neurologic disease, its implementation seems rational when faced with one or more horses with confirmed clinical EHV-1 infection (any form) at a particular facility. Whereas booster vaccination of horses that are likely to have been exposed already is not recommended, it is rational to booster vaccinate unexposed horses, as well as those that must enter the premises, if they have not been vaccinated against EHV-1 during the previous 90 days. Use of the Rhinomune modified live vaccine or one of the inactivated EHV-1 vaccines known to stimulate high circulating titers of neutralizing antibody appears justified for this purpose. Horse owners must develop an understanding of the concept of boosting herd immunity to help protect the individual horse rather than focusing on the as yet unattainable expectation that the veterinarian can reliably protect an individual horse from developing potentially fatal EHM by administering one of the vaccines currently marketed as aids to prevention of clinical manifestations of EHV-1 infection. Ultimately, enforcement of strict biosecurity measures and hygiene practices is likely to be more effective than widespread vaccination in reducing the risk of acquiring infection.

48.7 FUTURE VACCINATION STRATEGIES TO PREVENT HERPESVIRUS INFECTION

In order for vaccination to be completely effective in blocking primary infection and establishing a lifelong carrier state with EHV-1 and EHV-4, future vaccination strategies should be directed at inducing a strong mucosal immune response in the upper respiratory tract during the first few weeks of life, at a time when high levels of maternal antibodies are present. Promising progress toward this goal was reported recently by Patel and colleagues,[131] who documented that intranasal administration of a single dose of temperature-sensitive modified live EHV-1 vaccine to maternal antibody—positive foals aged 1.4 to 3.5 months afforded partial but significant protection against febrile respiratory disease, viremia, and virus shedding after intranasal challenge with virulent EHV-1 performed 8 weeks after vaccination.[131] This vaccine has also been shown to provide significant protection against abortion in challenge studies, and because it is capable of preventing the development of viremia, shows potential to prevent EHM.[112,132] Recent studies with vaccinia and canarypox-vectored

recombinant vaccines and DNA vaccines have generated promising results, but more research will be needed to identify the immunodominant protective antigens of EHV-1 and their interaction with the equine immune system before these approaches will be applicable for use in the field.[133–136]

48.7.1 *Streptococcus equi* subsp. *equi* Infection (Strangles)

Strangles is a highly contagious disease caused by the bacterium *S. equi* subsp. *equi*. Strangles primarily affects young horses (weanlings and yearlings), although horses of any age can become infected if not protected by previous exposure to the organism or by vaccination. The organism is transmitted by direct contact with infected horses or subclinical carriers or indirectly by contact with water troughs, feed bunks, pastures, stalls, trailers, tack, or grooming equipment contaminated with nasal discharge or pus draining from lymph nodes of infected horses. The organism survives for several weeks in the environment, particularly in aquatic locations and when protected from exposure to sunlight and disinfectants, and can be a source of infection for new additions to the herd. Because *S. equi* is a clonal organism, there is minimal antigenic variation among different isolates, even though isolates vary in their pathogenicity.

1581

1582

Most horses develop a solid immunity during recovery from strangles, which persists in over 75% of animals for 5 years or longer,[137] indicating that induction of durable protection through vaccination is biologically feasible if the protective antigens can be identified and presented in an appropriate manner.[138] Although the basis for acquired resistance to strangles is not completely understood, the finding that recovered horses rapidly clear intranasally inoculated *S. equi* despite not making circulating antibody to its surface proteins indicates that to be highly effective a strangles vaccine must stimulate local nasopharyngeal tonsillar immune clearance responses and that serum antibody is of lesser importance.[139] This conclusion is further supported by the finding that ponies with high levels of circulating antibody to multiple unique surface-exposed and secreted proteins after systemic vaccination remained susceptible to challenge with *S. equi*.[139] The cell wall M protein of *S. equi* (SeM) is recognized in the acquired immune response to *S. equi* infection, a response that involves both production of local antibodies in the nasopharynx and circulating opsonophagocytic antibodies.[140–142] The predominant opsonophagocytic antibodies are of the IgGb subisotype but also include IgGa and IgA, whereas IgGb and later mucosal IgA predominate in nasopharyngeal secretions.[140,143]

Strangles vaccines licensed for use and marketed in North America include two inactivated, adjuvanted M-protein cell wall extracts (Strepvax II, Boehringer Ingelheim, and Strepguard with Havlogen, Intervet, prepared by extraction with hot acid or mutanolysin plus detergent, respectively) and one attenuated live vaccine (Pinnacle IN, Fort Dodge) derived from an unencapsulated mutant of *S. equi* for intranasal administration.[144] Infection of horses with *S. equi* continues to cause troublesome outbreaks of strangles throughout North America, despite the availability and widespread use of these vaccines, indicating that their efficacy is suboptimal.[145] M-protein vaccines induce a good opsonophagocytic antibody response in serum but a minimal mucosal IgA response, which likely accounts for the incomplete protection observed when they are used in the field.[140,146] However, data do exist to document that vaccination using injectable SeM vaccines reduces the attack rate and severity of strangles in herds with endemic infection.[146–148] The live intranasal vaccine has been shown to induce a relevant mucosal immune response and partial or complete protection but may do so without inducing a strong serologic response.[145,149] Because vaccinal organisms in the intranasal vaccine must reach the inductive sites for immunity in the pharyngeal and lingual tonsils, accurate vaccine delivery is critical to vaccine efficacy.

Vaccination against *S. equi* is not routinely recommended for pleasure or performance horses kept in low-risk situations, but it is a consideration for horses that are resident on, or being transported to, premises such as breeding farms where strangles is a persistent endemic problem or where a high risk of exposure is anticipated. The bacterial modified live vaccine is generally preferred over inactivated injectable vaccines for primary vaccination of foals and weanlings and for routine use in older horses that are at high risk for infection. On breeding farms, efforts should be concentrated on preventing infection of foals and weanlings by booster-vaccinating broodmares 4 to 6 weeks before foaling to maximize colostral content of antibodies. Whereas the intranasal vaccine has been shown to be safe for use in mares at all stages of pregnancy and can be used in mares in the face of an outbreak, it does not reliably stimulate high levels of circulating antibody. For this reason, intramuscularly administered inactivated SeM products are preferred for prefoaling booster immunization of mares. Antibodies of the IgG and IgA class recognizing the SeM are passively transferred to the foal through colostrum and are also present in the milk of immune mares.[150] Antibodies of predominantly the IgGb isotype are absorbed from colostrum and redistribute to the nasopharyngeal mucosa.[143] These IgGb antibodies, along with the SeM-specific IgA antibodies that are present in milk and passively coat the pharyngeal mucosa of nursing foals, provide protection to most nursing foals up to the time of weaning.[142,143,150] Resistance of nursing foals to strangles during the first few months of life appears to be mediated by IgGb antibodies in nasal secretions and milk and not by IgA.[150] Serologic (ELISA) responses to M-protein vaccines are poor in foals, most likely owing to the inhibitory effect of maternal antibodies.

Whereas the intranasal modified live vaccine may be less susceptible than the inactivated extract vaccines to MDA interference, this issue has not been investigated, and the manufacturer does not recommend administration of this vaccine to horses less than 9 months of age. Considering that on farms where strangles is endemic foals often become infected around the time of weaning, at 4 to 8 months of age, it is difficult to protect them if vaccination is delayed until 9 months of age. Therefore a reasonable compromise on breeding farms where the risk of strangles infection is high and mares are on a regular vaccination program would be to begin primary vaccination of foals using the intranasal live vaccine as early as 4 months of age. The recommended two-dose primary series administered 2 to 3 weeks apart should be followed by a third dose 3 to 4 months later and boosters at 6- to 12-month intervals thereafter, depending on risk of infection. The intranasal vaccine has been administered to foals as young as 5 or 6 weeks of age during outbreaks. If a vaccine is used in this manner, a third dose of the vaccine should be administered 2 to 4 weeks before the foal is weaned to optimize protection during this high-risk period. Although there are few reports of adverse effects attributable to use of the intranasal strangles vaccine in young foals, the inability of foals to mount an adequate mucosal IgA response during the first month of life and the potential for interference by maternal antibodies suggest that foals are unlikely to fully benefit from intranasal strangles vaccine administered before 4 months of age. When an inactivated M-protein vaccine is used for primary vaccination of foals, it is recommended that the initial series begin at 4 to 6 months of age, using three doses administered at 3- to 6-week intervals, followed by semiannual boosters for as long as high-risk conditions prevail.

Strangles vaccines should be administered only to healthy, nonfebrile horses free of nasal discharge and should not be administered to those that are known to have had recent direct exposure to clinically ill animals.[138] However, outbreaks of strangles generally persist for several months to more than 1 year, particularly on breeding farms where each foal crop adds new susceptible animals to the population. Therefore strangles vaccines are frequently administered in the face of an outbreak as an adjunct to management practices designed to bring outbreaks under control, and it is not always possible to accurately determine the exposure status of each horse. Under these circumstances the likelihood of preventing strangles is greatest for horses that have not yet been exposed and can be kept isolated from infected horses until 2 weeks after the vaccination protocol can

be completed. Horses that have been vaccinated previously will generate a response more rapidly than will naive horses. Similarly, the intranasal modified live vaccine is preferred over inactivated vaccines for immunization of naive horses in an outbreak because it is likely to generate a protective immune response more rapidly.

Injectable strangles vaccines tend to cause local reactions at the site of injection more often than do other equine vaccines. Injection in the gluteal muscles is not recommended because gravitational drainage along fascial planes can prove troublesome in the event that an abscess develops at the injection site. In addition, purpura hemorrhagica, a serious and sometimes life-threatening systemic immune complex (Arthus-type) vasculitis manifested as edema with or without petechial hemorrhages on mucosal surfaces, has been observed with low frequency in the weeks after administration of strangles vaccines. Inactivated extract vaccines are implicated more often than the intranasal modified live vaccine, but all strangles vaccines have the potential to induce purpura. The antigen present in immune complexes is SeM, along with antibodies of the IgA class. Because a high serum IgG titer against *S. equi* appears to be associated with an increased risk of developing purpura, routine testing for specific IgG antibodies using a commercially available ELISA test has been recommended as a means of preventing vaccine-associated purpura.[145] Horses with titers of 1:1600 or greater in the SeM ELISA and those known to have had strangles during the previous year should not be vaccinated.[145]

The bacterial modified live vaccine for intranasal administration will cause injection site abscesses if inadvertently injected IM. To avoid inadvertent contamination of other vaccines, syringes, and needles, it is advisable and considered good practice to administer all parenteral vaccines before handling and administering the intranasal strangles modified live vaccine. Other reported adverse responses after administration of the intranasal modified live vaccine include nasal discharge, submandibular or retropharyngeal lymphadenopathy with or without abscessation, limb edema, internal abscesses (bastard strangles), and purpura hemorrhagica. The overall frequency of adverse events is low but appears to be higher than reported to the manufacturer (4.8 per 10,000 doses). On the other hand, the majority of reported adverse events, including the development of nasal discharge, lymph node abscesses, and purpura hemorrhagica, occur in horses on farms with endemic or epidemic strangles. Therefore it is often uncertain whether the adverse event was caused by the vaccine or by a wild strain of *S. equi*.

48.8 RECENT DEVELOPMENTS IN STRANGLES VACCINES

The nonspecifically attenuated Pinnacle strain of *S. equi* was produced by chemical mutagenesis to induce random mutations throughout the bacterial genome.[41,151] Because the point mutations responsible for attenuation have not been defined specifically, the potential exists for back mutation and reversion to full virulence.[151] In contrast, the live attenuated vaccine strain TW 928 contained in a strangles vaccine (Equilis StrepE, Intervet) recently licensed in Europe was stably attenuated by targeted deletion of the *aroA* gene.[152] This allowed development of a companion PCR test that has been used in molecular epidemiologic studies to determine whether strangles in vaccinated horses was caused by the vaccine or by wild-type strains.[153] Although this development proves that targeted gene deletion is a promising route for generating stable candidate mutants for inclusion in future vaccines, the high residual virulence, unconventional route of administration (submucosal in the upper lip), and short DOI induced by Equilis StrepE will limit its use.

The incomplete protection afforded by bacterins and SeM extracts administered parenterally or by attenuated live vaccines administered intranasally or submucosally, and the undesirable side effects associated with some of these products, have prompted research to investigate other potential vaccine antigens and vaccination strategies. Promising results have recently been achieved in challenge studies involving horses vaccinated intramuscularly

and intranasally with combinations of the recombinant antigens EAG (a protein that binds α_2-macroglobulin, albumin, and IgG), CNE (a collagen-binding protein), and SclC (a collagen-like protein).[154]

48.8.1 Equine Monocytic Ehrlichiosis (Potomac Horse Fever)

Equine monocytic ehrlichiosis, also known as *Potomac horse fever*, is caused by *Neorickettsia risticii* (formerly *Ehrlichia risticii*). Originally described in 1979 as a sporadic disease affecting horses residing in the northeastern United States near the Potomac River, the disease has since occurred in horses in 43 states in the United States, three provinces in Canada (Nova Scotia, Ontario, and Alberta), South America (Uruguay, Brazil), Europe (the Netherlands, France), and India. The disease does not appear to be directly contagious, and it now appears that accidental ingestion of aquatic insects harboring metacercariae infected with *N. risticii* is at least one mode of transmission.[155] PHF is seasonal, occurring between late spring and early fall in temperate areas, with most cases in July, August, and September at the onset of hot weather. The disease may affect individual horses sporadically or cause outbreaks involving multiple horses. Foals appear to be at low risk for the disease. If PHF has been confirmed on a farm or in a particular geographic area, it is likely that cases will occur in future years. Documentation of the involvement of operculate freshwater snails and aquatic insects such as caddisflies and mayflies in the life cycle of *N. risticii* has permitted formulation of focused control measures directed at minimizing exposure of horses to the habitats occupied by these species during the summer and fall months when disease risk is highest in endemic areas.[155] Risk reduction is best accomplished by denying horses access to river banks, creek beds, and irrigation ditches, as well as pastures that have recently been flooded or flood-irrigated.

Recovery after natural infection with *N. risticii* induces a strong antibody response and durable protection from reinfection lasting 20 months or longer. However, the presence of antibodies does not necessarily correlate with protection, and cell-mediated responses likely play a crucial role.[156] A β-propiolactone inactivated host cell—free *N. risticii* vaccine protects mice against homologous challenge.[157] Several inactivated PHF vaccines for intramuscular administration (Mystique, Intervet; Potomavac, Merial; PotomacGuard, Fort Dodge; PHF-Gard, Pfizer; and Equovum PHF, Boehringer Ingelheim) are licensed for use in horses with the label claim that they aid in prevention of PHF. Two of these are also available combined with a rabies vaccine. None carry a label claim for prevention of abortion. The high rate of serious complications and mortality associated with this disease has been considered adequate justification for vaccinating horses residing in or traveling to endemic areas. In a series of studies in which ponies were challenged IV with *N. risticii* approximately 4 weeks after completion of the two-dose primary vaccination series using a formalin-inactivated, aluminum hydroxide—adjuvanted vaccine (PHF-Vax, Schering-Plough), Ristic and colleagues (1988) reported that 78% of experimentally infected ponies were protected against all clinical manifestations of disease except fever, and 33% were protected against all signs, including fever.[158] A published noncontrolled field study involving the same vaccine documented induction of serologic responses in most vaccinated horses and a substantial reduction in disease prevalence, morbidity, and mortality compared with data collected in a previous year when horses were not vaccinated.[156,159]

1583
1584

In contrast to the results of the studies cited above, an epidemiologic investigation involving a large number of horses failed to demonstrate any clinical or economic benefit from annual vaccination with currently available vaccines in New York State.[160,161] Failure of a substantial number of individual horses to mount an immune response to inactivated PHF vaccines, heterogeneity of *N. risticii* isolates, the presence of only one *N. risticii* strain in vaccines, and much more rapid waning of immunity after vaccination than after natural infection likely account for the observed failure of vaccines to provide protection against field infection.[156,162] Despite the lack

of documented efficacy of approved vaccines to prevent infection in the field setting, many practitioners who work in endemic areas believe that severity of disease is attenuated and mortality is reduced in vaccinated horses when vaccines are administered at 4- to 6- month intervals, with administration of one booster timed to precede the anticipated period of peak challenge.

If vaccination is elected, a primary series of two doses should be administered 3 to 4 weeks apart. Manufacturers recommend revaccination at 6- to 12-month intervals; however, some veterinarians encourage a revaccination interval of 4 months in order to achieve a reasonable likelihood of protection. Because the disease has a distinct seasonal pattern, revaccination in the late spring, approximately 1 month before the first cases are expected, followed by a second dose 4 months later appears to be a reasonable approach for strategic immunization to maximize the chances of protection during the period of peak challenge. Available vaccines are licensed for use in stallions and pregnant mares and can be administered to gestating mares 4 to 8 weeks before foaling to maximize passive transfer of specific antibodies to foals through colostrum. Whereas approximately 67% of foals from antibody-positive mares were antibody negative by 12 weeks of age, antibody was detectable in 33% of foals up to 5 months of age. On the basis of these findings, the low risk of clinical disease in young foals, and the apparent susceptibility to infection of two foals vaccinated earlier than 12 weeks of age, primary vaccination of foals from antibody-positive dams should begin with a two-dose primary series starting 5 months of age or older, followed by administration of one subsequent booster dose 8 to 12 weeks later.[159] However, the efficacy of this recommended regimen requires further study. If the primary series of two vaccinations is initiated before 5 months of age, additional doses should be administered at monthly intervals up to 5 months of age to ensure that an immunologic response is achieved. Vaccination of foals in endemic areas is further complicated by the distinct seasonal incidence of disease in July, August, and September, a time when most foals are aged between 2 and 6 months and may be subject to maternal antibody interference with vaccination.

48.8.2 Botulism

Botulism is a neuromuscular paralytic disorder caused by one of eight distinct neurotoxins (A, B, Ca, Cb, D, E, F, G) produced by *Clostridium botulinum*, a soil-borne, spore-forming, saprophytic, anaerobic, gram-positive bacterium.[163] Botulinum toxins are among the most potent biologic toxins known and act by blocking transmission of impulses at motor endplates, resulting in weakness progressing to paralysis, inability to swallow, and frequently death. Of the seven serogroups (A through G) of *C. botulinum*, types A, B, C, and D have been reported to cause disease in horses, with types B and C being responsible for most cases.[163] Three forms of botulism—toxicoinfectious botulism (shaker foal syndrome), forage poisoning, and wound botulism—have been observed in horses. Forage poisoning results from ingestion of preformed toxin produced by decaying plant material or animal carcasses present in feed, whereas “wound botulism” results from vegetation of spores of *C. botulinum* and subsequent production of toxin in contaminated wounds. Shaker foal syndrome results from toxin produced by vegetation of ingested spores in the intestinal tract. Currently toxicoinfection with *C. botulinum* type C is being investigated as a cause of equine grass sickness, a largely fatal, pasture-associated dysautonomia affecting horses mainly in Great Britain, continental Europe, and Australia, with reports of isolated cases in the United States. Almost all cases of shaker foal syndrome are caused by type B. Shaker foal syndrome is a significant problem in foals aged 2 weeks to 8 months in Kentucky and in the mid-Atlantic seaboard states and occurs sporadically in other areas.[164–166]

A toxoid vaccine (BotVax-B, Neogen Corporation, Tampa, Fla.) directed against *C. botulinum* type B is licensed for use in horses in the United States. Its primary indication is prevention of the shaker foal syndrome via colostral transfer of antibodies induced by vaccination of the mare. For primary vaccination, mares should

be vaccinated during gestation with a series of three doses administered 4 weeks apart, scheduled so that the last dose will be administered 4 to 6 weeks before foaling to enhance concentrations of specific immunoglobulin in colostrums (i.e., months 8, 9, and 10 of gestation). Subsequently, mares should be revaccinated annually with a single dose 4 to 6 weeks before foaling. A similar type B toxoid is available to protect foals in endemic areas in Australia.[167]

Passively derived colostral antibodies appear to protect most foals for 8 to 12 weeks, although foals from properly vaccinated dams can develop botulism.[165–167] Insufficient production of specific antibody by the dam in response to the vaccination, failure of passive transfer of specific immunity to botulinum toxin, overwhelming toxin production, and loss of passive immunity by the time exposure to the toxin occurs may be reasons for vaccine failure. The clinician should therefore be aware of the status of MDA transfer of each foal.

Maternal antibodies do not appear to interfere with the response of foals to primary immunization against botulism[168]; therefore a primary series of three doses of vaccine administered 4 weeks apart can be started when foals in endemic areas are 2 to 3 months of age or older. Other horses can be immunized using a primary series of three doses of vaccine administered at 4-week intervals, followed by annual revaccination. Currently there are no licensed vaccines available for preventing botulism caused by *C. botulinum* type C or other subtypes of toxins, and cross-protection between the B and C subtypes does not occur; therefore routine vaccination against *C. botulinum* type C is not currently practiced. A type C toxoid approved for use in mink was administered to horses under special license to protect them during an outbreak of forage poisoning caused by contaminated alfalfa cubes in southern California in 1989.

Horses and foals with clinical botulism may be treated with botulinum antitoxin administered IV. Antitoxin is not effective against toxin that has been translocated to motor endplates. Therefore clinical signs may progress for 12 to 24 hours after administration of the antitoxin or until all internalized toxin has attached to motor endplates. The dose of botulinum type B antitoxin recommended for treating a foal is 30,000 IU and for an adult is 70,000 IU. Foals of unvaccinated mares born in or being moved to endemic areas may benefit from transfusion with plasma from a vaccinated horse or from administration of *C. botulinum* type B antitoxin. The efficacy of these practices needs further study. Vaccination with type B toxoid as described previously is an alternative to passive immunization.

1585

48.8.3 Equine Viral Arteritis

EVA is a contagious disease of equids caused by equine arteritis virus (EAV), an RNA virus that is found in the horse populations of many countries. EAV is the prototype virus in the family Arteriviridae of the genus Arterivirus, order Nidovirales. Although all horse breeds appear to be equally susceptible to EAV, the prevalence of infection, as determined by seroconversion, is much higher in some breeds, notably standardbreds and warmbloods, than in others. Despite the high seroprevalence of infection in standardbreds, clinical disease is rarely observed in this breed, indicating that subclinical infection is common.[41,169] Conversely, thoroughbreds and most other breeds have a low seroprevalence of infection but are more likely to show fulminant clinical signs when they become infected. Most primary EAV infections are subclinical or asymptomatic. Clinical signs, if they occur, typically develop 3 to 7 days postinfection and vary in severity, both within and between outbreaks, but may include some or all of the following: fever; anorexia; depression; dependent edema involving the limbs, prepuce, scrotum, mammary glands, or ventrum; localized or generalized urticaria; supraorbital or periorbital edema; conjunctivitis; lacrimation; and serous or mucoid nasal discharge. EAV is of special concern because abortion is a frequent sequela to infection in the unprotected pregnant mare. In addition, EAV can cause life-threatening pneumonia or pneumoenteritis in young foals, and infection of the

postpubertal colt or stallion may establish a long-term carrier state.[41,170] Transmission most frequently occurs through direct or aerosol contact with virus-infective respiratory secretions, leading to widespread dissemination of the virus among susceptible horses in close proximity. Indirect transmission, although less significant, can occur through contact with virus-infected fomites. Venereal transmission from infected carrier stallions to mares via semen during natural breeding or artificial insemination with fresh, chilled, or frozen semen can play a significant role in introduction and spread of infection on or between breeding farms or other equine facilities. The virus can persist in the reproductive tract of stallions for many years and possibly result in lifelong infection.

Historically, large-scale outbreaks of EVA have been relatively infrequent. However, the number of confirmed occurrences appears to be increasing, likely as a result of increased global movement of horses, increased accessibility of carrier stallions, and increased use of shipped cooled or frozen virus-infected semen. Outbreaks can be associated with serious economic consequences, as clearly exemplified by the 2006 multistate outbreak in quarter horses that was propagated by widespread shipment of semen from the index cases, two inapparently infected carrier stallions in New Mexico. Because the carrier stallion is widely accepted as the natural reservoir of EAV and the source of diversity among naturally occurring strains of the virus, identification of these individuals through serologic testing, followed by PCR testing or virus isolation from semen, forms the cornerstone of eradication measures. Vaccination also constitutes an important means of controlling spread and minimizing the consequences of infection.

A modified live vaccine based on an attenuated strain of EVA virus was developed by researchers in Kentucky in 1969.[171] This vaccine (Arvac, Fort Dodge Animal Health, Fort Dodge, Iowa) was first used extensively in the field during the 1984 outbreak of EVA in Kentucky and proved to be safe and effective in bringing the outbreak under control.[41] Subsequently this vaccine was developed further and licensed for use in North America. Vaccination of stallions, nonpregnant mares, and prepubertal colts has been shown to be a safe and effective means of controlling EVA. Strategic use of the modified live vaccine has formed the cornerstone of a highly successful program to control EVA in the Kentucky thoroughbred breeding population for many years.[41]

The indications for vaccination against EVA are as follows:

- To protect stallions against infection and subsequent development of the carrier state.
- To immunize seronegative mares before they are bred with EAV-infective semen.
- To curtail outbreaks in nonbreeding populations. Vaccination in the face of an EVA outbreak in concentrated populations of performance horses at racetracks has been successful in controlling horizontal disease dissemination within 7 to 10 days.

Primary immunization with the modified live vaccine involves intramuscular administration of a single dose, with a booster administered annually thereafter. VN antibodies are induced within 5 to 8 days after modified live virus vaccination and persist for at least 2 years.[41,172] Revaccination induces high VN antibody titers that persist for several breeding seasons.[172] Although the current modified live vaccine is highly attenuated and has been shown to be safe and effective in stallions and nonpregnant mares, a small proportion of first-time—vaccinated horses develop mild febrile reactions and transient lymphopenia after vaccination with the modified live vaccine, and vaccine virus may be isolated sporadically from the nasopharynx and buffy coat for 7 days but occasionally up to 32 days after vaccination.[41,172–174] Vaccinated stallions do not shed vaccine virus in either semen or urine.[172]

Primary vaccination provides sustained clinical protection against EVA but does not prevent reinfection and subsequent limited replication and shedding of field strains of virus.[175] However, in vaccinates the frequency, duration, and amount of viral shedding via the respiratory tract are significantly less than observed with natural infection. Vaccinated mares may shed field virus transiently after being bred to carrier stallions; therefore isolation of these individuals for 21 days after breeding is recommended.[41]

Annual revaccination of breeding stallions 28 days before the start of breeding season is highly recommended as a means of preventing establishment of the carrier state.[41] Annual revaccination of mares being bred to carrier stallions should occur at least 21 days before breeding. The modified live vaccine is not recommended for use in pregnant mares, especially during the last 2 months of gestation, or in foals less than 6 weeks of age, except in emergency situations when there is a high risk of exposure. Apparent fetal infections with modified live vaccine after vaccination of pregnant mares have been documented, but only rarely.[172,176]

Foals born to seropositive mares become seropositive after ingesting colostrum. MDAs decay with a mean half-life of approximately 32 days, with the result that foals become seronegative between 2 and 7 months of age.[177,178] Maternal antibodies are unlikely to interfere with the response to vaccine administered at 7 months of age or older.[177] However, when foals less than 6 months of age are vaccinated during conditions of high risk, they should be revaccinated after 6 months of age. Establishment of the carrier state appears to depend on the high levels of androgens circulating in intact stallions and can be prevented by vaccinating colts, preferably before puberty, before they are used for breeding.[41] Vaccination of prepubertal colts at 6 to 12 months of age is therefore central to effective control of the spread of EAV infection and should be strongly encouraged in breeds such as standardbreds and warmbloods in which EVA is prevalent and on facilities on which risk of infection is high. Persistent infection has never been documented in a stallion that was properly vaccinated with the licensed modified live vaccine before exposure.[41]

1585

1586

48.9 REGULATORY AND EXPORTATION CONSIDERATIONS WITH VACCINATION AGAINST EQUINE VIRAL ARTERITIS

In planning a vaccination program against EVA, it is important to consult with state and/or federal animal health officials to ensure that any such program is in compliance with the state's control program for EVA, if one exists. Because it is not possible to differentiate a vaccine-induced antibody response from that due to natural infection, it is strongly recommended that before vaccination all first-time male vaccinates be tested and confirmed negative for antibodies to EAV by a USDA-approved laboratory (www.aphis.usda.gov/cvbapps/Labs.jsp). Mares intended for export should be similarly tested. When there is uncertainty or concern over whether vaccination against EVA could prevent the export of a horse to a particular country, it is advisable to consult the federal area veterinarian (www.aphis.usda.gov/vs/area_offices.htm#CO) in charge in the state to determine the specific import requirements of that country. Several countries bar entry of any equid that is serologically positive for antibodies to EAV, regardless of vaccination history. Countries that do accept EVA vaccinated horses regardless of gender typically require stallions or colts to have a certified vaccination history and confirmation of prevaccination negative serologic status.

48.10 FUTURE DIRECTIONS

A killed-virus vaccine (Artervac, Fort Dodge Animal Health) is licensed for use in the United Kingdom, Ireland, France, Denmark, and Hungary, and a killed-virus vaccine is also used in Japan. As with the modified live vaccine

licensed in the United States, serologic responses to these inactivated vaccines cannot be distinguished from those resulting from natural infection. Development and marketing of a marker vaccine that not only affords protection but also allows vaccinated horses to be distinguished serologically from inapparently infected carriers would greatly facilitate control, and even eradication, of EAV from horse populations. Several "new generation" EAV vaccines that potentially meet these criteria have been developed in recent years. These include a modified live virus DIVA vaccine with a deletion in the GP5 ectodomain,[179,180] a DNA vaccine that incorporates open reading frames (ORFs) 2b, 5, and 7,[181,182] and a subunit EAV vaccine using recombinant replicon particles derived from a vaccine strain of VEE virus that includes genes encoding both major envelope proteins (GP5 and M) of EAV.[183,184]

48.10.1 Rotaviral Diarrhea

Equine RV, a nonenveloped RNA virus, is one of the most important causes of infectious diarrhea in foals during the first few weeks of life and often causes outbreaks involving the majority of the foal crop on individual farms.[185–187] Older foals and adult horses are more resistant to infection. Equine RV is transmitted via fecal-oral contamination and causes diarrhea by damaging the tips of villi in the small intestine, resulting in cellular destruction, maldigestion, malabsorption, and diarrhea. The genus Rotavirus is one of five genera of the family Reoviridae and is divided into seven serogroups (A through G) based on differences in the inner capsid protein, VP6.[187,188] All equine RV isolates to date are in group A, which is further subdivided using neutralizing antibodies to the VP4 and VP7 outer capsid proteins into P (protease-sensitive, VP4-positive) and G (glycoprotein, VP7-positive) serotypes, respectively.[188] Five P serotypes (P1, P6, P7, P12, and P18) and eight G serotypes (G1, G3, G5, G8, G10, G13, G14, and G16) have been identified and characterized in horses.[189–191] Most equine RV isolates from all parts of the world are, however, of the P12 and G3 serotype and include 2 subtypes (A and B).[192] A number of RV isolates remain untyped, so it is possible that other equine RV serotypes, and perhaps other serogroups, are active in the equine population.

An inactivated RV A vaccine (Equine Rotavirus Vaccine, Fort Dodge Animal Health, Fort Dodge, Iowa) containing the G3, P12 serotype (H2 strain) in a metabolizable oil-in-water emulsion is conditionally licensed in the United States and is indicated for administration to pregnant mares in endemic areas as an aid to prevention of diarrhea in their foals caused by infection with RVs of serogroup A. Foal vaccination is not indicated because there are no data to suggest that vaccination of the newborn foal with inactivated RV A vaccine has any benefit in preventing or reducing the severity of infection. Label recommendations call for a three-dose series of the vaccine to be administered to mares during each pregnancy at 8, 9, and 10 months of gestation. This protocol has been shown to induce significant increases in serum concentrations of neutralizing antibody in vaccinated mares and in the concentrations of antibodies of the IgG, but not IgA, subclass in the colostrum and milk of vaccinated mares.[193,194] It is essential that the newborn foal receive an adequate amount of good-quality colostrum so that it absorbs sufficient anti-RV antibodies. After nursing, the concentration of passively derived RV-specific antibody of the IgG subclass in the serum of foals up to 90 days of age from vaccinated mares is significantly higher than that measured in serum of foals born to unvaccinated mares.[193,194] A field study showed this vaccine to be safe when administered to pregnant mares and provided circumstantial evidence of at least partial efficacy. An approximately twofold higher incidence of rotaviral diarrhea was found in foals from unvaccinated mares compared with those from vaccinated mares, although this difference did not prove to be statistically significant.[193] Similarly, a controlled field study in Argentina in which an inactivated aluminum hydroxide—adjuvanted vaccine containing the SA11 (G3P2), H2 (G3P12), and Lincoln (G6P1) strains was administered to 100 mares at 60 days and again at 30 days before foaling demonstrated a substantial reduction in the incidence and severity of rotaviral disease in foals from vaccinated mares compared with foals

from unvaccinated mares.[195] As MDA titers wane at approximately 60 days of age, foals may develop rotaviral diarrhea. However, the severity of diarrhea is generally milder and of shorter duration than occurs in foals that become infected during the first 30 days of life.

Challenge studies involving two inactivated RV vaccines administered in a similar manner to pregnant mares in Japan showed that their foals were not completely protected against infection but had a substantial reduction in severity of clinical signs after challenge.[189] The major correlate for protection against rotaviral infection appears to be mucosal immunity, predominantly mucosal IgA, in the gastrointestinal tract. Studies of the immunoglobulin isotype responses of mares and of antibodies passively transferred to their foals after parenteral vaccination of their dams with inactivated RV vaccines indicate that this approach is unlikely to provide foals with intestinal mucosal protection in the form of IgA.[194] Consequently it is not surprising that current protocols do not provide complete protection. In addition, because the conditionally licensed vaccine available in the United States contains only the G3 serotype of the A serogroup, it cannot be expected to protect against infection with all field strains.

48.10.2 Equine Protozoal Myeloencephalitis

EPM is a multifocal neurologic disease caused by the apicomplexan parasites *Sarcocystis neurona* and, less often, *Neospora hughesi*. Serologic studies indicate that exposure to *S. neurona* occurs in most regions of North America, and in some areas seroprevalence exceeds 50%. Prevalence of clinically apparent neurologic disease caused by *S. neurona* and *N. hughesi* is much lower than the prevalence of antibodies, indicating that many horses become infected and mount an immune response that is effective in clearing infection before substantial damage occurs in the central nervous system. It is not known whether all seropositive horses have experienced neural infection or whether the immune response in these individuals is successful in clearing parasites before neural invasion occurs. The life-cycles of *S. neurona* and *N. hughesi* have not been determined definitively, although opossums are a definitive host for *S. neurona* and horses are likely dead-end hosts that inadvertently become involved in the life cycle.[196]

1586 1587

There is widespread exposure of horses in North America to *S. neurona* and a high level of owner concern (in some cases hysteria) within the equine industry, leading to the perception that EPM is of high economic importance. This, coupled with inadequate diagnostic techniques for antemortem confirmation of EPM and the suboptimal effectiveness of current treatment and control protocols, led the USDA to grant a conditional vaccine license to Fort Dodge Laboratories in 2000. This vaccine is an inactivated whole-parasite *S. neurona* vaccine with a metabolizable oil adjuvant (EPM Vaccine, Fort Dodge Animal Health) that has met USDA requirements for quality assurance and purity in the manufacturing process. The criteria for safety were also met in a field study involving vaccination of more than 700 horses. The manufacturer met the requirement for documenting “a reasonable expectation of efficacy” by demonstrating seroconversion in vaccinated horses using a plaque reduction assay to measure neutralizing antibodies. Subsequent studies in which indirect fluorescent antibody testing (IFAT) and immunoblot (IB) tests were used to measure humoral responses, and intradermal skin testing and peripheral blood mononuclear cell proliferation assays were used to assess cell-mediated immunity (CMI), documented seroconversion and sensitization of CMI in a high proportion of vaccinated horses.[197,198]

Development of a clinically relevant experimental model for *S. neurona* infection has proven to be difficult; therefore the efficacy of this vaccine has not been determined in experimental challenge studies or in prospective controlled double-blind field studies. Because antibody to *S. neurona* is detectable in the cerebrospinal fluid (CSF) as well as blood of some horses postvaccination,[197] prospective field efficacy studies

will be difficult to complete because one of the criteria now used to confirm a diagnosis—the presence of antibodies detectable by IB testing or IFAT in CSF not contaminated with blood—will be rendered invalid in vaccinated horses. This vaccine has not gained widespread use, even though it may ultimately prove to be effective in preventing EPM. However, such use has inevitably generated controversy within the veterinary and scientific communities. In addition, one of the most useful aspects of currently available serologic tests, the finding of a negative IB test or IFAT result to rule out a diagnosis of EPM, will be invalidated in vaccinated horses. The vaccine manufacturer has indicated that a modified IB procedure currently being tested may be effective in differentiating vaccinated horses from those that have experienced natural exposure. It is hoped that answers to these questions and concerns will be revealed in the future.

48.10.3 Anthrax

Anthrax is a serious and rapidly fatal septicemic disease caused by proliferation and spread of the vegetative form of *Bacillus anthracis* in the body. *B. anthracis* is acquired through ingestion, inhalation, or skin penetration through contamination of wounds by soil-borne spores of the organism. Anthrax is encountered only in limited geographic areas where moist alkaline soils, particularly those with high organic content, favor survival, germination, and sporulation of the organism. Vaccination is indicated only for horses pastured in endemic areas.

The only vaccine currently licensed for vaccination of livestock, including horses, contains viable live Sterne's strain 34F2 nonencapsulated spores in saponin (Anthrax Spore Vaccine, Colorado Serum Company, Denver, Colo.). A primary series consisting of two doses of that vaccine should be administered subcutaneously 2 to 3 weeks apart followed by annual revaccination. Mild to moderate swelling at the injection site is common, and adverse systemic reactions may occur occasionally, particularly in young and miniature horses. Little objective information is available regarding use of this vaccine in horses, but clinical evidence suggests that it provides protection; however, vaccination of pregnant mares is not recommended.[199] Because the vaccine is a live bacterial product, appropriate caution should be used during storage, handling, and administration to prevent accidental inoculation of people and to maintain vaccine potency. Concurrent administration of antimicrobial drugs that are effective against *B. anthracis* is contraindicated if the vaccine is to function as intended.

48.11 OVINE AND CAPRINE VACCINATION PROGRAMS

Nancy East

Joan Dean Rowe

Several commercially available vaccines are labeled for sheep or goats. Some cattle vaccines are used off label in these ruminants, but little critical evaluation is available regarding the efficacy of this practice. The same general considerations presented for bovine vaccination programs apply to programs for sheep or goats. The vaccines available for sheep and goats are listed in Table 48-5. It is important to compare the cost of vaccination with projected losses from the disease, especially in commercial sheep operations, because of the low individual animal value and the high cost of vaccines. When considering the use of expensive vaccines, such as those for foot rot, the high labor cost associated with the disease must be taken into account in addition to the more obvious cost of the disease. Flock health records, regional diagnostic laboratories, local veterinarians, and county extension agents are good resources for obtaining information about disease prevalence in a particular area.

The subcutaneous route is the preferred route for sheep or goat vaccines. The preferred site is the neck or behind the elbow, away from superficial regional lymph nodes. In sheep, injections should not be given in the loin or

hindquarters because this area makes up three fourths of the prime carcass cuts. Subcutaneous injections over the ribs in goats often cause unsightly, persistent granulomas.

Compliance with a vaccination program is best achieved if the program is designed around the times when livestock normally are handled. The major problems and errors that occur in vaccination programs are (1) failure to provide adequate booster doses of clostridial vaccines, (2) inappropriate handling of modified live virus bluetongue vaccines, (3) vaccination of ewes in early gestation with modified live virus bluetongue vaccines, (4) use of contagious ecthyma vaccines on uninfected premises, and (5) failure to obtain diagnosis of causes of abortion.

All sheep and goats should be vaccinated against *Clostridium perfringens* types C and D and tetanus with one of the available commercial products. Some of the multiway clostridial vaccines are less expensive than the *C. perfringens* types C and D/tetanus toxoid combination and are used for this reason rather than because of any real need for protection from the other diseases. The available clostridial toxoids tend to vary both in efficacy and the extent of adverse reactions (especially vaccination site granulomas). There is some indication that *C. perfringens* toxoids may be less effective in goats than in sheep. Annual vaccination of pregnant ewes and does with a *C. perfringens* types C and D/tetanus toxoid combination approximately 4 weeks before parturition confers adult flock immunity and maximizes passive transfer of antibody to newborn lambs and kids. These antibodies protect up to 4 to 6 weeks of age, through the high-risk period for *C. perfringens* type C enterotoxemia and for tetanus from customary husbandry procedures (castration, tail docking, and disbudding). 1587 1588

Table 48-5 Vaccines and Antisera Available for Sheep and Goats[a]

Disease or Organism	Vaccine Product Name
Enzootic abortion of ewes (EAE, *Chlamydophila abortus*, formerly *Chlamydia psittaci*)	*C. psittaci* bacterin[b]
Vibriosis (*Campylobacter fetus* subsp. *fetus*, *Campylobacter jejuni*)	*C. fetus* bacterin[b]
Bluetongue	Modified live serotypes 10,[b,c] 11,[c] 17[c]
Foot rot	Footvax, *Bacteroides nodosus* bacterin[d]
	Volar, *Fusobacterium necrophorum* bacterin[e]
Clostridium tetani/*Clostridium perfringens* combination toxoids (many contain additional clostridia)	Bar Vac CD/T[f]
	C. perfringens types C and D, tetanus toxoid[b]
	Covexin 8[d]
	Vision CD-T[e]
	Caseous DT[b] (*C. perfringens* type D, tetanus toxoid, and *C. pseudotuberculosis*) Various other combinations and brands are available
Anthrax *(Bacillus anthracis)*	Anthrax spore vaccine[b] Various combinations and brands are available
Contagious ecthyma (sore mouth, orf) (live viral vaccine)	Ovine ecthyma vaccine[b]
Brucella ovis (ram epididymitis)	*B. ovis* (ram epididymitis) bacterin[b]
Caseous lymphadenitis *(Corynebacterium pseudotuberculosis)*	Case-Bac (*C. pseudotuberculosis* bacterin toxoid[b])
Tetanus antitoxin	Tetanus antitoxin[g]
C. perfringens antitoxin (A, B, C, D available)	*C. perfringens* types C and D antitoxin[b]
Rabies	Imrab, Imrab 3[h] Prorab-1[e] Rabdomun[d]

a Many additional vaccines manufactured for use in cattle can be used safely in sheep and goats when the need arises.

g Widely available.

h Merial, Inc., Athens, GA. 30607.

Adverse reactions to combination clostridial, *Campylobacter*, and *Chlamydophila* vaccines are not unusual, especially when these vaccines are given at the same time as foot rot vaccine or vitamin E—selenium injections. Particularly in purebred flocks, owners should be taught the clinical signs and treatment of adverse reactions, which can occur 30 minutes to longer than 12 hours after vaccination. Adverse reactions include localized swelling, stiffness, pyrexia, anorexia, pulmonary edema and respiratory distress (foaming at the nose and mouth), laminitis, bloating and groaning, abortion (2 to 7 days after vaccination), and sudden death. Vaccination granulomas may persist.

Campylobacter species vaccination is recommended in sheep annually, whereas *Chlamydophila abortus* (formerly *Chlamydia psittaci*) vaccination is used in affected flocks or herds 2 to 4 weeks before the breeding season. *C. abortus* vaccine is of low efficacy when administered to pregnant ewes or does. Rams and bucks should receive annual boosters in affected herds.

The use of bacterins of *Leptospira interrogans* in sheep and goats is of questionable value under most circumstances. It is difficult to induce abortion in susceptible females with experimental infection. In endemic areas when sheep and cattle are grazed together or are adjacent and drink groundwater from streams or irrigation runoff, explosive outbreaks of leptospirosis in young growing lambs and occasional abortion storms in pregnant ewes have been described.

The cattle vaccines most commonly used in sheep are those directed against the respiratory disease complex; these vaccines are the intranasal infectious bovine rhinotracheitis (IBR) vaccine, the bovine respiratory syncytial virus (BRSV) vaccine, the killed or modified live virus *Pasteurella* vaccines, and the killed bovine virus diarrhea (BVD) vaccines. Justification of the use of these vaccines is based on current understanding of the possible potentiating and synergistic role of the cattle respiratory virus complex in ovine pneumonia and the prevalence of antibody to these viruses in the North American sheep population. Few well-controlled clinical trials using respiratory complex vaccines have been completed. Many respiratory problems can be best controlled by changes in management (see Chapter 31). Various vaccines for *Mannheimia haemolytica* pneumonia are marginally efficacious.

Table 48-6 shows a sheep vaccination schedule and flock management calendar for ewes and lambs in North America, and Table 48-7 shows a schedule and calendar for rams. Geographic differences in the distribution of endemic disease dictate which vaccine protocols are most economic and efficacious. Vaccines recommended for sheep include those that immunize against the following diseases or pathogens:

1588

1591

- Foot rot
- *C. abortus* (enzootic abortion of ewes [EAE]; formerly *C. psittaci*)
- *Campylobacter* species (vibriosis)
- Bluetongue virus (endemic areas only)
- Contagious ecthyma (sore mouth; infected premises or outbreak only)
- *C. perfringens* types C and D
- *C. tetani* (tetanus)

- Other clostridial agents as needed

Table 48-6 Ewe and Lamb Vaccination Schedule and Flock Management Calendar for North America

Procedure	Prebreeding	Breeding	Tag or Shear	Lambing	Lamb Growth	Shearing	Weaning
Vaccination*	EAE (*Chlamydophila* species) *Vibrio (Campylobacter)* species	*Vibrio* booster	Vaccinate bagged ewes with clostridial caseous DT or eight-way clostridial and footrot vaccine	Footrot vaccination booster in yearling ewes	Clostridial vaccination (caseous DT) or eight-way vaccine for 6- to 10-week-old lambs		Vaccinate feeder lambs against clostridial agents
	Bluetongue						
Parasite control (see Chapter 49)	Deworm		Deworm if indicated	Soremouth vaccine for lambs on endemic premises	Give clostridial booster 4 weeks later; use caseous DT for replacement ewes		Vaccinate replacement ewes with caseous DT
Treatment	Vitamin E and selenium if needed		Vitamin E and selenium if needed		Coccidiostat in creep feed or salt to young lambs	Control external parasites	Deworm feeder lambs
					Deworm older lambs		
Reproduction	Condition score ewes, separate and flush; check udders, cull undesirables Check for lameness, treat as needed	30 to 60 days after breeding, check for pregnancy and cull open ewes Supplement pregnant ewes if thin	Separate ewes in late pregnancy, and supplement last 4 weeks of gestation	Dock lamb tails Castrate excess male lambs		Sell fat lambs	Identify and cull ewes: Thin Missing or loose teeth (incisors or molars) or molar points Chronic mastitis Dry ewes (no lamb) Poor mothers Chronic lameness

EAE, Enzootic abortion of ewes.
